August 21, 2012

Summary. In conditionally heteroskedastic models, the optimal prediction of powers, or logarithms, of the absolute value has a simple expression in terms of the volatility and an expectation involving the independent process. A natural procedure for estimating this prediction is to estimate the volatility in a first step, for instance by Gaussian quasi-maximum likelihood (QML) or by least-absolute deviations, and to use empirical means based on rescaled innovations to estimate the expectation in a second step. This paper proposes an alternative one-step procedure, based on an appropriate non-Gaussian QML estimator, and establishes the asymptotic properties of the two approaches. Asymptotic comparisons and numerical experiments show that the differences in accuracy can be important, depending on the prediction problem and the innovations distribution. An application to indexes of major stock exchanges is given.

Keywords: Efficiency of estimators, GARCH, Least-absolute deviations estimation, Prediction, Quasi maximum likelihood estimation.

A version of this article (without Appendix B) is forthcoming in the Journal of the Royal Statistical Society, Series B.

We are most thankful to the Joint Editor, Ingrid Van Keilegom, and to two referees for their constructive comments and suggestions. We are also grateful to the Agence Nationale de la Recherche (ANR), which supported this work via the Project ECONOM&RISK (ANR 2010 blanc 1804 03).
Predictions of powers of ARCH

1. Introduction

Despite the considerable attention given to the autoregressive conditional heteroscedasticity (ARCH) model and its generalization, the GARCH model, relatively few papers have examined the issue of forecasting. Engle and Kraft (1983) considered predictions of ARMA processes with ARCH errors. Engle and Bollerslev (1986) and Baillie and Bollerslev (1992) studied predictions of the conditional mean in ARMA model with GARCH errors, and prediction of conditional variances in GARCH\((p,q)\) models. Andersen and Bollerslev (1998) discussed the predictive qualities of GARCH, making a clear distinction between the prediction of volatility and that of the squared returns. Karanasos (2002) considered predicting the conditional mean and variance from an ARMA model with GARCH in mean effects. Pascual, Romo and Ruiz (2005) proposed a Bootstrap procedure to obtain prediction densities of returns and volatilities of GARCH processes. Pelligrini, Ruiz and Espasa (2012) analyze the effects of differencing GARCH with stochastic trend on the prediction intervals.

In this paper, our aim is to investigate the problem of predicting powers of the process \((\epsilon_t)\), defined as a solution of the general stochastic model

\[
\begin{cases}
\epsilon_t = \sigma_t \eta_t \\
\sigma_t = \sigma(\epsilon_{t-1}, \epsilon_{t-2}, \ldots; \theta_0)
\end{cases}
\]

where \((\eta_t)\) is a sequence of independent and identically distributed (iid) random variables, \(\eta_t\) being independent of \(\{\epsilon_u, u < t\}\), \(\theta_0 \in \mathbb{R}^m\) is a parameter belonging to a parameter space \(\Theta\), and \(\sigma : \mathbb{R}^\infty \times \Theta \rightarrow (0, \infty)\). The variable \(\sigma_t^2\) is generally referred to as the volatility of \(\epsilon_t\) in the econometric literature.\(^2\)

Most conditional volatility models can be embedded in Model (1). A leading model, the most widely used among practitioners, is the GARCH\((1,1)\) model where

\[
\sigma_t^2 = \omega_0 + \alpha_0 \epsilon_{t-1}^2 + \beta_0 \sigma_{t-1}^2
\]

and \(\theta_0 = (\omega_0, \alpha_0, \beta_0)' \in (0, \infty) \times [0, \infty) \times [0, 1)\). For this model we have \(\sigma_t^2 = \sum_{i=1}^{\infty} \beta_i - 1 (\omega_0 + \alpha_0 \epsilon_{t-i}^2)\) which is of the form (1). Other specifications satisfying (1) are the GARCH\((p,q)\), the asymmetric power GARCH\((p,q)\) model proposed by Ding, Granger and Engle (1993), and the ARCH\((\infty)\) introduced by Robinson (1991). In GARCH models, it is generally assumed that \(E\eta_t = 0\), but we do not make this assumption.

1.1. Two approaches for predicting powers

For any real number \(r\) such that \(E|\eta_t|^r < \infty\), the best predictor in mean square of \(|\epsilon_t|^r\) is the conditional expected value

\[
E_{t-1}(|\epsilon_t|^r) = \sigma_t^r E|\eta_t|^r,
\]

where \(E_{t-1}\) denotes expectation conditional on the infinite past. We will also consider the optimal prediction of \(\log |\epsilon_t|\) given by

\[
E_{t-1}(\log |\epsilon_t|) = \log \sigma_t + E \log |\eta_t|,
\]

provided that \(E \log |\eta_t|\) exists. This case can be seen as the limit of the case (2) when \(r = 0\), via the Box-Cox transformation \(\log |x| = \lim_{r \to 0} (|x|^r - 1)/r\).

\(^2\)The choice of an appropriate GARCH model, including the orders, is clearly an important issue: see for instance Li (Chapter 6, 2004) for diagnostic tests in GARCH models, and Francq and Zakoïan (Chapter 5, 2010) for the selection of GARCH orders.
To estimate the volatility in Model (1) a scale constraint is required on the sequence \( (\eta_t) \), for evident identifiability reasons. The standard assumption \( E\eta_t^2 = 1 \) is required for the consistency of the Gaussian quasi-maximum likelihood estimator (QMLE), while the least absolute deviations estimator (LADE) requires the condition \( \text{median}(\eta_t^2) = 1 \). However, the constraint \( E|\eta_t|^r = 1 \), with \( r \neq 0 \), can be used as well. In view of this, we consider two approaches for predicting \( |\epsilon_{n+1}|^r \), given observations \( (\epsilon_1, \ldots, \epsilon_n) \):

- A fully parametric one-step approach in which \( \theta_0 \) is estimated under the assumption that \( E|\eta_t|^r = 1 \) when \( r \neq 0 \), and \( E\log|\eta_t| = 0 \) when \( r = 0 \). The prediction of \( |\epsilon_{n+1}|^r \) (resp. \( \log|\epsilon_{n+1}| \)) based on (2) (resp. (3)) is then the estimated value of \( \sigma_{n+1}^r \) (resp. \( \log\sigma_{n+1} \)).

- A mixed (parametric and non parametric) two-step approach in which \( \theta_0 \) is estimated by the practitioner’s favorite estimator under a relevant identifiability assumption (for instance the QMLE under \( E|\eta_t|^2 = 1 \), or the LADE under \( \text{median}(\eta_t^2) = 1 \)), and \( E|\eta_t|^r \) (or \( E\log|\eta_t| \) when \( r = 0 \)) is estimated non-parametrically. The prediction of \( |\epsilon_{n+1}|^r \) (resp. \( \log|\epsilon_{n+1}| \)) based on (2) (resp. (3)) is the estimated value of \( \sigma_{n+1}^r \) (resp. \( \log\sigma_{n+1} \)) multiplied by the estimate of \( E|\eta_t|^r \) (resp. plus the estimate of \( E\log|\eta_t| \)).

The mixed approach seems more natural. Many statistical procedures include two steps, involving the estimation of a characteristic of the error distribution in the second step. Examples include Generalized Least Squares (the errors variance), adaptive estimation (the errors density) and value-at-risk estimation in GARCH-type models (a quantile of the errors distribution). The fully parametric approach is novel, to our knowledge, and, as we shall demonstrate, it can provide efficiency gains over the more natural approach.

1.2. Non Gaussian QML

For the reparameterized model under the identifiability constraint \( E|\eta_0|^r = 1 \) with \( r \neq 2 \), the QMLE is generally inconsistent. For our prediction problem with \( r \neq 2 \), we therefore consider a generalized QMLE based on an instrumental density \( f \) different from the Gaussian. This QMLE coincides with the MLE when the error’s distribution \( f \) is correctly specified (that is when \( h = f \)). To keep the robustness of the standard QML, it should also be consistent for any error distribution \( f \) satisfying \( E|\eta_0|^r = 1 \). This will imply a choice of \( h \) depending on the prediction problem, that is on \( r \). Newey and Steigerwald (1997) studied the identification conditions required for the consistency of non Gaussian QMLE’s in general conditional heteroskedastic models. In the case of standard GARCH models, Berkes and Horváth (2004) derived the asymptotic distribution of such estimators. Fan, Qi and Xiu (2010), and Francq, Lepage and Zakoian (2011) proposed two-stage procedures based on non Gaussian QMLE for estimating standard GARCH models under the standard identifiability condition. In the latter references, alternative QML criteria are introduced to achieve better efficiency than the Gaussian QMLE. By contrast, in the fully parametric approach of the present paper, the QML criterion will be imposed by the prediction problem under consideration.

1.3. Interest of predicting powers \( r \neq 2 \)

The prediction of \( \epsilon_n^2 \), which is also the prediction of the volatility under the assumption that \( E\eta_t^2 = 1 \), is obviously important for financial applications but it does not appear to be sufficient.
Predictions of powers of ARCH

i) Interest of considering \( r > 2 \). The conditional moments of financial returns are an important measure of the market fluctuation. The conditional kurtosis, defined as the ratio of the fourth conditional moment over the squared volatility has drawn attention in the finance literature (see for instance Brooks, Burke, Heravi and Persand (2005) and the references therein). Conditional distributions of financial series typically display a sharp peak around zero as well as fat tails. To measure the fluctuations of tails, it is therefore sensible to evaluate how \( E_{t-1}(\epsilon_t^4)/\{E_{t-1}(\epsilon_t^2)\}^2 \) varies with time. If the GARCH model is correctly specified, this ratio should be constant. Estimation of the conditional kurtosis can thus be the basis of a formal specification test. In this paper we focus on the estimation of such conditional moments and leave this issue for further investigation.

ii) Interest of considering \( 0 \leq r < 2 \). As argued by Taylor (2007, p. 398), "return outliers are amplified when they are squared and then forecast errors are typically very large compared with other times. Consequently another popular proxy [of volatility] is the absolute return." Indeed, when one suspects that second or fourth-order moments do not exist, it is sensible to consider predictions of absolute returns, or even smaller powers of returns as measures of the future price volatility.

iii) Interest of considering \( r < 0 \). For some applications, for instance duration time between events, it may be worth fitting a GARCH-type model to the inverses of the data. Autoregressive conditional duration (ACD) models were introduced by Engle and Russell (1998) for the analysis of durations. ACD can be seen as squares of GARCH models applied to duration data, \( x_t \) say (where \( t \) denotes the \( t \)-th transaction, and \( x_t \) the duration between the \( (t-1) \)-th and \( t \)-th transactions). Such models are appropriate to capture the clustering of large durations: a GARCH effect is detected if the empirical correlations between present and past durations, \( \hat{\text{Corr}}(x_t, x_{t-k}) \) for \( k > 0 \), say, are significant. However, it may be of interest to capture clustering of small durations. Indeed, such small durations are likely to reflect high volatility of prices. If significant empirical correlations between present and past inverse durations, \( \hat{\text{Corr}}(x_t^{-1}, x_{t-k}^{-1}) \) for \( k > 0 \), are found, it is thus sensible to adjust a GARCH model to the inverse of such duration data, \( \epsilon_t = 1/x_t \). The usual GARCH methodology allows to optimally predict \( \epsilon_t^2 \), but one is mostly interested in predicting \( x_t \) or \( x_t^2 \). To this aim, we need to predict \( |\epsilon_t|^r \) with \( r = -1 \) or \( r = -2 \). In the supplementary document, we present an empirical example showing that such significant autocorrelations are detected for the inverses of durations between transactions.

1.4. Contributions of this paper

For the general Model (1), we study the aforementioned methods for predicting \( |\epsilon_{n+1}|^r \) or \( \log |\epsilon_{n+1}| \). For the first step of the mixed procedure, we focus on two methods: the Gaussian QMLE and the LADE.

Our main contributions are the following: 1) we introduce the one-step method, based on a generalized QML; 2) we obtain a complete characterization of the omnibus instrumental densities, that is those which render the generalized QMLE universally consistent; 3) the asymptotic properties of the generalized QMLE are derived for Model (1); 4) the asymptotic properties of the mixed approach are derived; 5) for the standard GARCH model, we obtain surprisingly simple expressions for the Asymptotic Relative Efficiency (ARE) of the fully parametric method with respect to mixed methods in which either the QML or the LAD estimation is used in first step.
1.5. Organization of the paper

Section 2 is devoted to the strong consistency and asymptotic normality (AN) for generalized QMLE, based on an instrumental density \( h \), in Model (1). The choice of \( h \) is solved for the prediction problems (2)-(3), by characterizing the functions \( h \) for which the consistency is achieved under a given condition \( E\left|\eta_0\right|^r = 1 \) or under the condition \( E \log \left|\eta_0\right| = 0 \). Section 3 is devoted to the asymptotic properties of the two-step approach based on the Gaussian QML. For the standard GARCH\((p, q)\), we show that the ARE of the one-step estimator only depends on the power \( r \) and moments of the iid process. Section 4 completes the comparison of the two approaches, by considering the LADE, instead of the Gaussian QMLE, for the two-step method. Section 5 proposes empirical applications based on financial data. The most technical assumptions and proofs are deferred to Appendix A. Complementary results, proofs and illustrations are collected in Appendix B.

2. Asymptotic properties of non-Gaussian QMLE

The asymptotic results of this paper will be established under the following assumption, which can be made more explicit for specific forms of the volatility function \( \sigma \) (for classical GARCH see Nelson (1990), Bougerol and Picard (1992)).

**A0:** \( (\epsilon_t) \) is a strictly stationary and ergodic solution of (1).

Given observations \( \epsilon_1, \ldots, \epsilon_n \), and arbitrary initial values \( \tilde{\epsilon}_i \) for \( i \leq 0 \), we define \( \tilde{\sigma}_t(\theta) = \sigma(\epsilon_{t-1}, \epsilon_{t-2}, \ldots, \epsilon_1, \tilde{\epsilon}_0, \tilde{\epsilon}_1, \ldots; \theta) \). This random variable will be used as a proxy of \( \sigma_t(\theta) = \sigma(\epsilon_{t-1}, \epsilon_{t-2}, \ldots, \epsilon_1, \epsilon_0, \epsilon_{-1}, \ldots; \theta) \). We choose an arbitrary integrable and positive function \( h \), in general a density, which can be called instrumental density, and define the QML criterion

\[
\tilde{Q}_n(\theta) = \frac{1}{n} \sum_{t=1}^{n} g(\epsilon_t, \tilde{\sigma}_t(\theta)), \quad g(x, \sigma) = \log \frac{1}{\sigma} h\left(\frac{x}{\sigma}\right).
\]

Let the QMLE

\[
\tilde{\theta}_{n,h} = \arg \max_{\theta \in \Theta} \tilde{Q}_n(\theta)
\]

for some compact space \( \Theta \). This estimator is the standard Gaussian QMLE when \( h \) is the standard Gaussian density \( \phi \).

2.1. Identifiability conditions

To be able to identify the parameters in Model (1) it is necessary to impose a constraint on \((\eta_t)\). For the sake of predicting \( |\epsilon_t|^r \), a natural constraint in view of (2)-(3), is

**A1:** \( E|\eta_0|^r = 1 \) when \( r \neq 0 \), and \( E \log |\eta_0| = 0 \) when \( r = 0 \).

We make the following assumption on the volatility function, for some \( \omega > 0 \).

**A2:** Almost surely, \( \sigma_t(\theta) \in (\omega, \infty] \) for any \( \theta \in \Theta \). Moreover, \( \sigma_t(\theta_0)/\sigma_t(\theta) = 1 \) a.s. iff \( \theta = \theta_0 \).

For the consistency of the estimator \( \tilde{\theta}_{n,h} \), we assume that the function \( \sigma \rightarrow Eg(\eta_0, \sigma) \) is valued in \([-\infty, +\infty)\) and has a unique maximum at 1:

**A3:** \( Eg(\eta_0, \sigma) < Eg(\eta_0, 1) \quad \forall \sigma > 0, \quad \sigma \neq 1. \)
Let $f$ denote the density of $\eta_0$, when existing. To interpret A3, denote by $K(f, f^*) = E\log(f/f^*)(\eta_0)$ the Kullback-Leibler "distance" between $f$ and a density $f^*$. Let $h_\sigma(x) = \sigma^{-1} h(\sigma^{-1}x)$, the density of $\sigma Y$ where $Y$ has the density $h$. Then A3 can be written

$$K(f, h) < K(f, h_\sigma), \quad \forall \sigma > 0, \quad \sigma \neq 1.$$ 

This condition means that there is no way to obtain a density closer to $f$ by scaling $h$. It is clear by the Jensen inequality that A3 is always satisfied for the MLE, that is if $h = f$. However, in general $f$ is unknown and cannot be chosen as the instrumental density. When $h \neq f$, A3 entails a moment condition on $\eta_0$, which may be incompatible with A1. For instance when $h = \phi$, we find that A3 reduces to $E\eta_0^2 = 1$. This condition is compatible with A1 only when $r = 2$. It is therefore important to characterize the functions $h$ which make A1 and A3 compatible. This will be done in Section 2.3.

2.2. Asymptotic properties of the generalized QMLE

Apart from identifiability assumptions, technical conditions are required for the asymptotic properties of the generalized QMLE. Let $H_0$ be the set of the instrumental densities $h > 0$ which are differentiable over $\mathbb{R}^* = \mathbb{R} \setminus \{0\}$. For some constants $\delta \in \mathbb{R}$ and $C_0 > 0$, let

A4: $h \in H_0$ with $|u h'(u)/h(u)| \leq C_0(1 + |u|^r)$ for all $u \in \mathbb{R}^*$ and $E|\eta_0|^\delta < \infty$.

A5: For any $x \in \mathbb{R}^m$, we have: $x' \left( \frac{\partial \sigma^2}{\partial \theta} \right)_{i=1,\ldots,m} = 0$, a.s. $\Rightarrow$ $x = 0$.

A4 is a mild assumption which vanishes for instance when the instrumental density has the form $h(u) = K_1 |u|^\lambda \exp\{K_2 |u|^\lambda\}$, for some constants $\lambda, K_1, K_2$. In this case, the inequality is satisfied with $\delta = r$ and the condition $E|\eta_0|^\delta < \infty$ thus follows from A1. Assumption A5 is required for the invertibility of the matrix $J$ involved in the asymptotic variance of the estimator. For specific forms of $\sigma_t$, for instance if the model is a standard GARCH, the condition reduces to standard assumptions on the lag polynomials of the volatility. For the reader’s convenience, additional technical assumptions, A6-A10, are reported in the appendix. The following is an extension of results (Theorems 1.1 and 1.2) proven by Berkes and Horváth (2004) for the standard GARCH.

**Theorem 2.1.** If A0-A4 and A6 hold, for constants $\delta \in \mathbb{R}$ and $C_0 > 0$, then

$$\hat{\theta}_{n,h} \to \theta_0, \quad \text{a.s.}$$

where $\theta_0$ is the true parameter value in Model (1) under the identifiability condition A1. If, in addition, A7-A10 hold and $Eg_2(\eta_0, 1) \neq 0$ then

$$\sqrt{n} \left( \hat{\theta}_{n,h} \theta_0 \right) \xrightarrow{\mathcal{D}} \mathcal{N}(0, 4\tau_{h,f}^2 J^{-1})$$

where

$$J = J(\theta_0) = E \left( \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2}{\partial \theta} \frac{\partial \sigma_t^2}{\partial \theta} \right)(\theta_0) \quad \text{and} \quad \tau_{h,f}^2 = \left\{ \frac{E g_2(\eta_0, 1)}{E g_2(\eta_0, 1)^2} \right\}^2,$$

with $g_1(x, \sigma) = \partial g(x, \sigma)/\partial \sigma$ and $g_2(x, \sigma) = \partial g_1(x, \sigma)/\partial \sigma$. 

This result contains, as particular cases, the AN for the MLE (when \( h = f \)) and for the QMLE (when \( r = 2 \) and \( h = \phi \)). In the former case we have

\[
\tau^2_{f,f} = \left\{ E \left( 1 + \frac{f'(\eta_0)}{f(\eta_0)} \eta_0 \right)^2 \right\}^{-1}.
\]

We also have \( \tau^2_{\phi,f} = (E\eta_0^4 - 1)/4 \) when \( r = 2 \) and we retrieve the standard result.

**Remark 1.** The results of Theorem 2.1 can be compared with those obtained in other articles for the Gaussian QMLE of general formulations similar to (1). Straumann and Mikosch (2006) studied the Gaussian QMLE for conditionally heteroscedastic models where the volatility has the form \( \sigma^2_t = g(\epsilon_t-1,\ldots,\epsilon_{t-p},\sigma^2_{t-1},\ldots,\sigma^2_{t-q};\theta) \). More recently Bardet and Wintenberger (2009) proved the asymptotic properties of the Gaussian QMLE for a general class of multidimensional causal processes encompassing (1). However, their conditions for consistency and AN require the existence of moments of orders 2 and 4 for \( \epsilon_t \), respectively, which we do not need for the class (1). Our sole moment assumptions are on \( \eta_t \). For GARCH processes, the existence of moments for \( \eta_t \) does not imply finite moments for \( \epsilon_t \); see for instance Figures 2.8 and 2.10 in Francq and Zakoian (2010).

**Remark 2.** These results can also be compared with those, already mentioned in the introduction, using non Gaussian QMLE. Except in the case \( r = 2 \), our parameter \( \theta^*_0 \) is not the GARCH parameter, denoted by \( \theta^*_0 \) in the sequel (see Equation (6)), which is estimated in the aforementioned articles. Fan, Qi and Xiu (2010) propose a method for estimating \( \theta^*_0 \) in the standard GARCH model, using a very general QML and two optimization procedures. For the same models and the same parameter \( \theta^*_0 \), the approach of Francq, Lepage and Zakoian (2011) only requires one optimization procedure but uses more specific QMLs.

### 2.3. Choice of the instrumental density

A given function \( h \) can be said to be omnibus for our prediction problem if Assumptions A1 and A3 are compatible for any distribution of \( \eta_0 \). In this section, we will show that under A4, the class of the omnibus functions \( h \) reduces, for a given \( r \), to the class \( \mathcal{C}(r) \) of functions of the form

\[
\begin{cases}
    c|x|^\lambda - 1 \exp(-\lambda|x|^r/r), & \text{if } r > 0, \\
    c|x|^{-\lambda - 1} \exp(\lambda|x|^r/r), & \text{if } r < 0, \\
    \sqrt{\lambda/\pi}|2x|^{-1} \exp\left\{-\lambda(\log |x|)^2\right\}, & \text{if } r = 0,
\end{cases}
\]

for constants \( \lambda, c > 0 \). The following proposition, whose proof is straightforward, shows that, for a given \( r \), the QMLE based on \( h \in \mathcal{C}(r) \) does not depend on \( c \) and \( \lambda \).

**Proposition 1.** If the instrumental function \( h \) belongs to \( \mathcal{C}(r) \) then the generalized QMLE is given by

\[
\hat{\theta}_{n,h} = \begin{cases}
    \arg\min_{\theta \in \Theta} \sum_{t=1}^{n} \log \tilde{\sigma}_t^r(\theta) + \frac{|\epsilon_t|^r}{\tilde{\sigma}_t^r(\theta)}, & \text{if } r \neq 0, \\
    \arg\min_{\theta \in \Theta} \left\{ \sum_{t=1}^{n} \log \frac{|\epsilon_t|}{\tilde{\sigma}_t(\theta)} \right\}^2, & \text{if } r = 0.
\end{cases}
\]
Table 1. Choice of \( h \) depending on the prediction problem.

| Problem | constraint \( E_{\tau} |\epsilon|^r, \ r > 0 \) | solution \( \sigma^r \) | instrumental density \( h \) | \( \tau_{h,f} \) |
|---------|---------------------------------|-----------------|---------------------------|-----------------|
| \( E_{\tau} |\epsilon|^r, \ r > 0 \) | \( E |\eta|^r = 1 \) | \( \sigma^r \) | \( c|x|^{1/r} \exp(-\lambda|x|^r), \ \lambda > 0 \) | \( E_{|\eta|^r}^{2r-1} \) |
| \( E_{\tau} |\epsilon|^r, \ r < 0 \) | \( E |\eta|^r = 1 \) | \( \sigma^r \) | \( c|x|^{-1/r} \exp(\lambda|x|^r), \ \lambda > 0 \) | \( E_{|\eta|^r}^{2r-1} \) |
| \( E_{\tau} \log |\epsilon| \) | \( E \log |\eta| = 0 \) | \( \log \sigma^r \) | \( \sqrt{n} |\lambda| |\tau|^r \exp(\{\lambda|x|^r\}) \) | \( E(\log |\eta|)^2 \) |

The previous result shows that when \( r \neq 0 \), the non Gaussian QMLE can be interpreted as a standard QMLE obtained by transforming the data \( \epsilon^2 \) in \( |\epsilon|^r \). The following proposition shows that \( A3 \) can be omitted in Theorem 2.1 when \( h \) is chosen in \( C(r) \).

**Proposition 2.** Let \( h \in \mathcal{H}_0 \) be such that \( A4 \) holds. Then

\[ A3 \text{ holds for any distribution of } \eta_0 \text{ satisfying } A1 \quad \text{iff} \quad h \in C(r). \]

In view of Propositions 1 and 2, it is not restrictive to choose \( h \) in the set \( C(r) \) with \( \lambda = 1 \). The choice of the instrumental density \( h \) is thus entirely determined by \( r \), that is by the prediction problem. This is summarized in Table 1. The last column provides the factors \( \tau_{h,f}^2 \) which, by Theorem 2.1, measures the impact of \( h \) on the asymptotic variance of the QMLE.

The next result, which is established in the supplementary document, characterizes the set of densities \( f \) of \( \eta_r \) for which a given \( h \) is optimal.

**Corollary 1.** Let the assumptions of Theorem 2.1 hold for some \( h \in C(r) \). Then the generalized QMLE based on \( h \) coincides with the MLE when the density \( f \) of \( \eta_r \) belongs to \( C(r) \).

Conversely, when \( f \not\in C(r) \) but is such that \( \tau_{f,f}^2 \) exists, any generalized QMLE based on \( h \in C(r) \) is asymptotically inefficient in the sense that \( \tau_{f,f}^2 < \tau_{h,f}^2 \).

The loss of efficiency of the non Gaussian QMLE with respect to the ML is illustrated in Table 2 for Gaussian errors.

### 3. Mixed approach based on the Gaussian QML

The mixed approach involves two steps. In a first step, the model is estimated by the standard QMLE and, in a second step, the expectation involved in (2) (or (3)) is estimated using the estimated rescaled innovations. To obtain the asymptotic properties of this method, it is necessary to derive the joint asymptotic distribution of the estimators of the two steps.

When \( r = 0 \), the prediction of \( \log |\epsilon| \) is equivalent to the prediction of the conditional mean in the regression model \( y_t = \log \sigma(\theta_0) + \epsilon_t \), where \( y_t = \log |\epsilon_t| \) and \( \epsilon_t = \log |\eta_t| \). Gouriéroux, Monfort and Trognon (1984) showed that the consistent Pseudo maximum likelihood estimators (PMLE) are the minimizers of the objective functions \( \sum_{t=1}^n \log h(y_t, \log \sigma(\theta)) \), where \( h(x, m) \) belongs to the family of the linear exponential densities of mean \( m \). Such PMLE do not coincide with our QMLE because our estimator optimizes the likelihood of a scale parameter (see (4)) whereas the PMLE optimizes the likelihood of a location parameter.
The Gaussian QMLE of $\theta$ for $\theta$ is defined as a maximizer over $\Theta$ of $n^{-1}\sum_{t=1}^{n}\log \left[ \tilde{\sigma}_t^{-\epsilon}(\theta) \phi \left\{ \tilde{\sigma}_t^{-\epsilon}(\theta) \epsilon_t \right\} \right]$. Let the rescaled residuals $\tilde{\eta}_t^* = \epsilon_t / \tilde{\sigma}_t^*$, where $\tilde{\sigma}_t^* = \sigma(\epsilon_{t-1}, \epsilon_{t-2}, \ldots, \epsilon_0, \epsilon_1, \ldots, \epsilon_n)^. We define

$$
\hat{\mu}_t^* = \frac{1}{n} \sum_{t=1}^{n} |\tilde{\eta}_t^*|, \quad \mu_t^* = E|\tilde{\eta}_t^*|^r = \frac{1}{\mu_2^r}, \quad \text{for } r \neq 0,
$$

$$
\hat{\mu}_0^* = \frac{1}{n} \sum_{t=1}^{n} \log |\tilde{\eta}_t^*|, \quad \mu_0^* = E \log |\tilde{\eta}_t^*| = -\frac{1}{2} \log \mu_2, \quad \text{for } r = 0,
$$

and $\kappa_s = \frac{E|\eta_t|^r}{\mu_2^r}$ for any $s \neq 0$.

3.1. Asymptotic distribution of $(\hat{\theta}_n^*, \hat{\mu}_t^*)$

**Theorem 3.1.** If $\mathbf{A0-2}$, $\mathbf{B0}$, $\mathbf{B1}$ and, with $\delta = \max(2, r)$, $\mathbf{A6}$, $\mathbf{A9-A10}$ hold, and $\theta_0^* \in \Theta$, then $\hat{\theta}_n^* \rightarrow \theta_0^*, \hat{\mu}_t^* \rightarrow \mu_t^*$ a.s. and

$$
\left( \frac{\sqrt{n} \left( \hat{\theta}_n^* - \theta_0^* \right)}{\sqrt{n} \left( \hat{\mu}_t^* - \mu_t^* \right)} \right) \xrightarrow{d} \mathcal{N} \left\{ 0, \Sigma_r := \left( \begin{array}{cc} (\kappa_4 - 1)J_r^{-1} - \lambda_r J_r^{-1} \Omega_r & -\lambda_r J_r^{-1} \Omega_r \\ -\lambda_r J_r^{-1} \Omega_r & \sigma_{\mu_t}^2 \end{array} \right) \right\},
$$

where

$$
J_r = E \left( \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2(\theta_0^*)}{\partial \theta} \frac{\partial \sigma_t^2(\theta_0^*)}{\partial \theta} \right), \quad \Omega_r = E \left( \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2(\theta_0^*)}{\partial \theta} \right)
$$

and

$$
\lambda_r = \frac{r}{2} \kappa_r (\kappa_4 - 1) - (\kappa_{2+r} - \kappa_r), \quad \sigma_{\mu_t}^2 = \kappa_{2 + r} + \frac{r}{2} \kappa_r (\lambda_r - \kappa_{2 + r} + \kappa_r)
$$

for $r \neq 0$, and

$$
\lambda_0 = \frac{\kappa_4 - 1}{2} - \text{Cov} \left( \log |\eta_t|, \frac{\eta_t^2}{\mu_2} \right), \quad \sigma_{\mu_0}^2 = \text{Var} (\log |\eta_t|) + \lambda_0 - \frac{\kappa_4 - 1}{4}.
$$
To our knowledge, the mildest assumptions for the problem is thus to compare the asymptotic distribution for \( \hat{\kappa} \) suffice to compare the asymptotic distributions of \( \log \tilde{\sigma} \) when \( \theta \), \( \kappa \). The comparison can be explicitly done for the standard GARCH (0,1) model. The results of Theorem 2.1 are applied to the standard GARCH model and some of its extensions. This is the object of the next section.

In the proof, the following relation, of independent interest, is established:

\[
\Omega_\tau J_{s-1} \Omega_s = 1. \tag{8}
\]

To show this equality we use an argument based on asymptotic results. A direct proof, based on algebra, can be given in the standard GARCH case (see Appendix B).

Remark 3. In the proof of (8) it is shown that \( \hat{\kappa} \) is degenerate and \( \hat{\theta}_n \) has the same limiting normal distribution as \( \hat{\theta}_{n,\phi} \).

Remark 4. In the proof of (8) it is shown that \( \hat{\kappa} \), a.s. This entails that, when \( r = 2 \), the two approaches for predicting \( \epsilon_t^2 \) are the same. In this case, the asymptotic distribution for \( \hat{\kappa} \) is degenerate and \( \hat{\theta}_n \) has the same limiting normal distribution as \( \hat{\theta}_{n,\phi} \).

Remark 5. In the centered Gaussian case, \( \Sigma_r \) is block-diagonal. Indeed, if \( \eta_t \) follows a \( N(0, \sigma^{-2/r}_r) \) distribution where \( r > -1 \) and \( N_r = E[U]^r \) if \( U \) is \( N(0,1) \) distributed, then \( \kappa_4 = 3 \) and \( \kappa_s = (s-1)\kappa_{s-2} \) for \( s > 1 \). It follows that \( \lambda_r = 0 \).

3.2. Comparison of predictors

By the direct approach, based on the generalized QMLE \( \hat{\theta}_{n,h} \), the optimal prediction \( E_n | \epsilon_{n+1}^r \) is estimated by \( \hat{\sigma}^r(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_{n,h}) \). By the mixed approach, based on the Gaussian QMLE \( \hat{\theta}_n \) in Model (6), the same optimal prediction is estimated by \( \hat{\sigma}^r(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_n^r) \hat{\mu}_r = \hat{\sigma}^r(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_n^r, \hat{\mu}_r^r) \). The optimal prediction \( E_n \log | \epsilon_{n+1}^r | \) can similarly be estimated by \( \log \hat{\sigma}(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_{n,h}) \) and \( \log \hat{\sigma}(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_n^r) + \hat{\mu}_0 = \log \hat{\sigma}(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_n^r, \hat{\mu}_0^r) \). To compare the predictors it suffices to compare the asymptotic distributions of \( \hat{\theta}_{n,h} \) and \( \hat{\theta}_n \) in Model (6), the same optimal prediction is estimated by \( \hat{\sigma}^r(\epsilon_n, \epsilon_{n-1}, \ldots; \hat{\theta}_n^r, \hat{\mu}_0^r) \).

The problem is thus to compare

\[
4r_{n,h}^2 J_{n,h}^{-1} \quad \text{and} \quad \Gamma_n = \left[ \frac{\partial G_r(\theta_0^r, \mu_0^r)}{\partial (\theta^r, \mu^r)} \right] \Sigma_r \left[ \frac{\partial G_r(\hat{\theta}_0^r, \mu_0^r)}{\partial (\hat{\theta}^r, \hat{\mu}^r)} \right].
\]

The comparison can be explicitly done for the standard GARCH(p, q) model and some of its extensions. This is the object of the next section.

3.3. The standard GARCH(p, q) case

To our knowledge, the mildest assumptions for the \( \sqrt{n} \) consistency and AN of the Gaussian QMLE for standard GARCH with iid errors admitting a finite fourth-order moment were obtained by Berkes, Horváth and Kokoszka (2003) and Francq and Zakoian (2004). In this section, the results of Theorem 2.1 are applied to the standard GARCH(p, q) model

\[
\begin{align*}
\epsilon_t &= \sigma_t \eta_t \\
\sigma_t^2 &= \omega_0 + \sum_{i=1}^p \alpha_i \epsilon_{t-i}^2 + \sum_{j=1}^q \beta_j \sigma_{t-j}^2
\end{align*} \tag{10}
\]
of Theorem 3.2 the asymptotic variance matrices of the two estimators verify
asymptotic distributions of the estimators of this theorem reduce to those of the aforementioned papers.

The next theorem, which is proven in the supplementary document, provides the asymptotic distributions of the estimators of \( \theta_0 \) involved in the two methods.

**Theorem 3.2 (Standard GARCH\((p,q)\)).** Let \( r \neq 0 \). For \( h \in \mathbb{C}(r) \), \( E|\eta_0|^r = 1 \), \( E|\eta_0|^{2r} < \infty \) and under C, the one-step estimator of \( \theta_0 \in \hat{\Theta} \) satisfies

\[
\sqrt{n} \left( \hat{\theta}_{n,h} - \theta_0 \right) \xrightarrow{d} \mathcal{N} \left( 0, \left( \frac{2}{r} \right)^2 \left( \frac{\kappa_{2r}}{\kappa_r^2} - 1 \right) J^{-1} \right). \tag{11}
\]

Under the same assumptions and \( E|\eta_0|^{2r} < \infty \), the two-step estimator is given by \( \hat{\theta}_n = (\hat{\mu}_s, \hat{\alpha}_1^*, \hat{\beta}_p^*) \) and satisfies

\[
\sqrt{n} \left( \hat{\theta}_n - \theta_0 \right) \xrightarrow{d} \mathcal{N} \left( 0, (\kappa_4 - 1)J^{-1} + \left( \frac{2}{r} \right)^2 \left( \frac{\kappa_{2r}}{\kappa_r^2} - 1 \right) - (\kappa_4 - 1) \right) \|\hat{\theta}_0\| \tag{12}
\]

where \( \hat{\theta}_0 = (\theta_0^{[1, q+1]} \theta_0^{[1, q+1]}) = (\omega_0, \alpha_{0p}, \omega, \alpha_{0q}) \).

It is interesting to note that when applied to the Gaussian QML \((r = 2)\), the assumptions of this theorem reduce to those of the aforementioned papers.

The next result allows for a very simple comparison of the efficiencies of the two methods.

**Corollary 2 (A criterion for efficiency comparison).** Under the assumptions of Theorem 3.2 the asymptotic variance matrices of the two estimators verify

\[
\text{Var}_a \left\{ \sqrt{n} \left( \hat{\theta}_{n,h} - \theta_0 \right) \right\} \succeq \text{Var}_a \left\{ \sqrt{n} \left( \hat{\theta}_n - \theta_0 \right) \right\}
\]

in the sense of positive semi-definite matrices, if and only if

\[
\left( \frac{2}{r} \right)^2 \left( \frac{\kappa_{2r}}{\kappa_r^2} - 1 \right) \geq \kappa_4 - 1.
\tag{13}
\]

**Remark 6.** Surprisingly, the asymptotic efficiency comparison of the two approaches only depends on \( r \) and some moments of the iid process, not on \( \theta_0 \). This result has importance for practical purposes. It gives a basis for selecting the (asymptotically) more efficient method, as a function of \( r \) and estimated moments of \( \eta_0 \). From the rescaled residuals of a standard GARCH estimation, one can estimate \( \kappa_r \) empirically for any value of \( r \), and thus one should be able to infer which method is asymptotically the best. This will be illustrated in Section 5.
Remark 7. An analogous of Theorem 3.2 and Corollary 2 is established for the case $r = 0$ in the supplementary document. The two-step estimator is asymptotically more accurate than the one-step estimator when

$$4 \text{Var}(\log |\eta_0|) \geq \kappa_4 - 1.$$ 

It is also shown that the asymptotic variances of the two estimators are the limits of the asymptotic variances in Theorem 3.2 when $r$ goes to 0.

Figure 1 shows the ARE of the one-step QMLE relative to the two step QMLE as measured by the ratios

$$\frac{(\kappa_4 - 1)}{2^\kappa_4} \left( \frac{2r}{\kappa_4} - 1 \right) \quad \text{when } r \neq 0,$$

for Student distributions and Generalized Error Distributions (GED)\textsuperscript{5}, with parameter $\nu$. For Student distributions (left panel), it is seen that the one-step method outperforms the indirect one when $r \in (k_\nu, 2)$ for some constant $k_\nu$ ranging from 0 (when $\nu \leq 6$) to 1 (when $\nu = 14$). On the contrary, for $r > 2$ and small or negative values of $r$, the two-step approach is preferable. The differences are particularly remarkable for small value of $\nu$. As mentioned in Remark 7, the ARE’s in the case $r = 0$, displayed as bullets in the graph, are the limits of the ARE’s when $r$ approaches zero. For the GED, similar conclusions can be drawn for $r \leq 2$, but the direct method can be superior to the two-step approach for $r > 2$.

\textsuperscript{4}Note however that the term ARE does not refer here to the ratio of the asymptotic variances of two estimators.

\textsuperscript{5}The density of $\eta_0$ is of the form $f(x) \propto e^{-0.5|x|^{1/\nu}}$. 

Fig. 1. ARE of the one-step QMLE relative to the two step QMLE for Student distributions (left panel) and GED (right panel) with parameter $\nu$. 

---

**Predictions of powers of ARCH**
3.4. The Asymmetric Power GARCH\((p, q)\) case

The following nonlinear GARCH\((p, q)\) model was introduced by Ding, Granger and Engle (1993). Letting \(x^+ = \max(x, 0)\) and \(x^- = \min(x, 0)\) we set, for a given \(\delta > 0\),

\[
\begin{align*}
\epsilon_t &= \sigma_t \eta_t \\
\sigma_t^2 &= \omega_0 + \sum_{i=1}^{q} \alpha_{0i} (\epsilon_{t-i}^+)^\delta + \alpha_{0i-} (-\epsilon_{t-i}^-)^\delta + \sum_{j=1}^{p} \beta_{0j} \sigma_{t-j}^\delta
\end{align*}
\]

where \(\alpha_{0i+}, \alpha_{0i-}, \beta_{0j}\) are nonnegative coefficients, and \(\omega_0 > 0\). This model allows to capture the so-called "leverage effect", and generalizes models introduced by Higgins and Bera (1992), and Zakoïan (1994).

The study conducted for the standard GARCH model can be reproduced for the Asymmetric Power GARCH. The most striking output of this study is that the conclusion of Corollary 2 holds true for Model (14): the estimator \(\tilde{\theta}_n\) is asymptotically more efficient than \(\hat{\theta}_{n,h}\) iff (13) holds. The proof is in Appendix B.

4. Mixed approach based on LAD estimation

The proposed one-step method can be compared not only to the Gaussian QML, but also to estimation procedures developed in the literature which are known to be relatively efficient in the case of Non-Gaussian noise; see for instance Davis, Knight and Liu (1992) and Ling (2005) for the study of \(M\)-estimators for autoregressions with infinite variance, Mukherjee (2008) for the study of \(M\)-estimators for GARCH. In this section, we consider a special case of \(M\)-estimation, the LAD estimator defined and studied by Peng and Yao (2003) in the context of GARCH models. For simplicity, we focus on the standard GARCH\((p, q)\) model and \(r \neq 0\).

To derive the LADE we reparameterize the model (10) in such a way that the median of the squared innovation be equal to 1. Assume that

- \(C_0\): the density \(f_{\eta^2}\) of \(\eta^2\) is continuous and positive at \(M = \text{median}(\eta^2_t) > 0\) and \(E|\log \eta_t^2| < \infty\),

and let \(\eta_t^* = \frac{\eta_t}{\sqrt{M}}\). The LADE \(\hat{\theta}_n^* = (\hat{\omega}^*, \hat{\alpha}_1^*, \ldots, \hat{\beta}_p^*)\) of \(\theta_0^* = (M\omega_0, M\alpha_{01}, \ldots, M\alpha_{0q}, \beta_{01}, \ldots, \beta_{0p})'\), is defined as a minimizer over \(\Theta\) of

\[
\frac{1}{n} \sum_{t=1}^{n} \left| \log \epsilon_t^2 - \log \tilde{\sigma}_t^2(\theta) \right|.
\]

Let the rescaled residuals

\[
\hat{\eta}_t^* = \frac{\epsilon_t}{\sigma_t} \quad \text{where} \quad \hat{\epsilon}_t^* = \sigma(\epsilon_{t-1}, \epsilon_{t-2}, \ldots, \epsilon_{0}, \epsilon_{-1}, \ldots; \hat{\theta}_n^*).
\]

We define, for \(r \neq 0\),

\[
\hat{\mu}_r^{**} = \frac{1}{n} \sum_{t=1}^{n} |\hat{\eta}_t^*|^r, \quad \mu_r^{**} = E|\eta_t^*|^r.
\]

The next theorem, which is proven in the supplementary document, provides the asymptotic distributions of the two-step LADE of \(\theta_0\) and its comparison with the one-step estimator.
The two-step LAD predictor; (3) the one-step non-Gaussian QML predictor. In the available in Appendix B.

In this section we concentrate on the Threshold GARCH(1,1) model

\[ \epsilon_t = \sigma_t \eta_t, \quad \sigma_t = \omega_0 + \alpha_0 + (\epsilon_{t-1}^+) + \alpha_0(-\epsilon_{t-1}^-) + \beta_0 \sigma_{t-1}, \]  

with the notation and the assumptions of (14). Suppose that \( \epsilon_1, \ldots, \epsilon_n \) are observed, and consider three predictors of \( |\epsilon_{n+1}| \) or \( |\epsilon_{n+1}| \): (1) the two-step Gaussian QMLE; (2) the two-step LAD predictor; (3) the one-step non-Gaussian QML predictor. In the following, we propose an "adaptive" procedure for determining the best method and for computing the appropriate prediction in practice. Then, this procedure will be illustrated on real data and compared with cruder prediction methods. Simulation experiments are available in Appendix B.
5.1. Implementation of the adaptive prediction method
The procedure is described for Model (18) in the case \( r \neq 0 \). It can be straightforwardly modified when \( r = 0 \). In view of Section 3.4 and its direct extension to the LAD estimator, the algorithm works the same way for any model belonging to the standard or Asymmetric Power GARCH classes.

Step 1. Fit the TGARCH(1,1) model (18) by Gaussian QML.

Step 2. Compute the rescaled residuals \( \hat{\eta}_t^* = \frac{\epsilon_t}{\hat{\sigma}_t^*} \). Compute their empirical moments \( \hat{\mu}_r^*, \hat{\mu}_2^*, \hat{\mu}_4^* \). Compute the empirical median \( \hat{M}^* \), and estimate the density \( f_{n^*} \) (for instance by the Kernel method) of the squared residuals \( \hat{\eta}_t^{*2} \).

Step 3. Compute the quantities

\[
\begin{align*}
c_0 &= \frac{\hat{\mu}_2^*}{\hat{\mu}_2^*} - 1, \\
c_1 &= \left( \frac{2}{1} \right)^2 \frac{\hat{\mu}_2^*}{\hat{\mu}_2^*} - 1, \\
c_2 &= \frac{1}{\{2M^*f_{n^*}(M^*)\}^2}.
\end{align*}
\]

(i) If \( c_0 = \min_{i=0,1,2} c_i \), then the Gaussian QMLE can be preferred for the prediction of \( |\epsilon_{n+1}|' \). The prediction is computed as \( \hat{\sigma}_n^{***} \hat{\mu}_r^* \).

(ii) If \( c_2 = \min_{i=0,1,2} c_i \), then the LADE can be preferred. Reestimate the TGARCH(1,1) model by LAD,\(^6\) and compute the \( \hat{\eta}_r^{**} = \frac{\epsilon_t}{\hat{\sigma}_t^{**}} \). Compute their empirical moment \( \hat{\mu}_r^{**} \). The prediction of \( |\epsilon_{n+1}|' \) is \( \hat{\sigma}_n^{***} \hat{\mu}_r^{**} \).

(iii) If \( c_1 = \min_{i=0,1,2} c_i \), then the one-step estimator can be preferred. Reestimate the TGARCH(1,1) model by non-gaussian QML, by minimizing \( \sum_{t=1}^{n} \log \hat{\sigma}_t^2(\theta) + |\epsilon_t|' / \hat{\sigma}_t(\theta) \). The prediction of \( |\epsilon_{n+1}|' \) is \( \hat{\sigma}_n^{***} \).

Interestingly, the determination of the more efficient procedure in Step 3 can be based on the sole estimation by Gaussian QML. Note also that the numbers \( c_i \) are invariant by scale transformation of the residuals (which explains that \( c_3 \) is also an estimator of the number \( \xi_{n^*} \) of Theorem 4.1).

5.2. Empirical Illustration
We now consider prediction of powers on daily returns of 10 world stock market indices, namely the CAC, DAX, DJA, DJI, DJT, DJU, FTSE, Nikkei, SMI and SP500, from January 2, 1990, to October 13, 2011, for the indices for which such historical data exist. Note that this period of time includes the recent sovereign-debt crises in Europe and US. We checked that the results are not qualitatively changed by suppressing the recent turbulent period or by replacing the TGARCH model (18) by a standard GARCH(1,1). Before applying our procedure to these data, it is of interest to determine, for each series and each power \( r \), which method is asymptotically the best. This can be done by estimating the ARE of the one step-method with respect to the two-step methods, as derived in Section 3.2.

5.2.1. Estimating the ARE of the one-step and two-step methods
Figure 2 presents the estimated relative efficiencies of the one-step QMLE relative to the two step QMLE and LADE for the ten stock index returns. For the left panel, the TGARCH(1,1) model (18) is estimated by Gaussian QML in a first step. In a second step, the standardized residuals \( \hat{\eta}_t^* = \frac{\epsilon_t}{\hat{\sigma}_t^*} \) are computed, from which the ARE estimator, \( c_0/c_1 \), is computed (see Section 5.1). It is seen that, from an asymptotic point of view, the direct approach should

\(^6\)For instance \( (\hat{M}^* \hat{\omega}^*, \hat{M}^* \hat{\alpha}^*, \hat{\beta}^*)' \) can be used as initial value for the estimation of \( \theta_n^{**} \).
be superior for \( r \in (0.5, 2) \); the indirect one should be preferable for \( r > 2 \) or \( r < -0.5 \). For \( r \in (-0.5, 0.5) \) the results are more balanced. Turning to the right panel, the TGARCH(1,1) model (18) is now estimated by LAD in a first step, while the second step allows to compute the estimated AREs, \( c_2/c_1 \). The direct approach remains superior, for most series, when \( r \in (0.5, 2) \). For some series, it is also superior for values of \( r \) larger than 2. Conversely, the two-step method is preferable for the DAX series, whatever \( r \).

### 5.2.2. Out-of-sample comparisons

For predicting the power \( r \) of the next log-return, three competing methods are investigated: the "historical" prediction which predicts the next value by empirical means of observations to the power \( r \); the "naive" method\(^7\) which uses the power \( r/2 \) of the usual prediction of the squared return; the adaptive method described in Section 5.1.

Our numerical experiments setting is as follows, for each series \( \epsilon_t \) of length \( n \). Based on \( \epsilon_{n_2-n_1+1}, \ldots, \epsilon_{n_2} \), with \( 0 < n_1 \leq n_2 < n \), the historical prediction of \( |\epsilon_{n_2+1}|^r \) is computed from the formula

\[
\text{Historic}_{n_2+1} = \frac{1}{n_1} \sum_{t=n_2-n_1+1}^{n_2} |\epsilon_t|^r.
\]

The Mean Square Prediction Error (MSPE) is thus

\[
\frac{1}{n-n_1} \sum_{n_2=n_1}^{n-1} (|\epsilon_{n_2+1}|^r - \text{Historic}_{n_2+1})^2.
\]

\(^7\)the method can be called naive because it targets \( \{E_{t-1}(\epsilon_t^2)\}^{r/2} \) instead of \( E_{t-1}|\epsilon_t|^r \).
Table 3. Percentages of MSPE losses with respect to the best method, for prediction of $|e_{n+1}|^r$.

</table>

For the two other methods, $n_1$ observations are used to estimate the GARCH models and the appropriate moments. The same estimated model is kept for the computation of $n_3$ predictions.

For $n_1 = n_2 = n_3 = 300$, Table 3 displays the percentages of prediction losses with respect to the best method. For instance, for $r = 0$, the MSPEs of the CAC are 1.654 for the naive method, 1.380 for the historical method and 1.286 for the adaptive method. The adaptive method is thus the best in this case, implying a percentage of loss of 0, while the percentages of MSPE losses of the two other methods are $28.6 = 100 \times (1.654 - 1.286)/1.286$ and 7.3, respectively.

An outstanding feature of the results presented in Table 7 is that the adaptive method is superior in most cases to its competitors (as indicated by the presence of zeroes in the adaptive columns). Note that for $r = 2$, the naive method coincides with the two-stage Gaussian QML, and also with the generalized QML. As expected, the naive method is spurious for predicting powers which are very different from the square (in particular $r = 0$). The performance of the historical method is satisfactory for small values of $r$ but deteriorates as $r$ increases. Experiments conducted with 30 observations (instead of 300) in the sample means of the historical method lead to slightly better results (see Appendix B) for this method, which is however still generally dominated by the adaptive approach. The overall conclusion of this study is that the adaptive method performs well, the MSPEs being always smaller than (or very close to) those of the two other methods.

### 6. Conclusion

We have shown that, in conditionally heteroskedastic models, the optimal predictions of powers (or the logarithm) of the observed process can be estimated in one step, using a non Gaussian QML method applied to a reparameterization of the model. We obtained a complete characterization of the omnibus instrumental densities $h$ which render the generalized QMLE universally consistent. The asymptotic properties of the generalized QMLE are studied in a quite general framework. We also derived the asymptotic properties of alternative two-step approaches which combine Gaussian QML or LAD estimation in a first

---

8The adaptive method, in the case $r = 2$, sometimes chooses the LAD method which explains that the results for the adaptive method do not coincide with those of the naive method.
step, and estimation of the $r$-th order moment of the innovations in a second step.

In the case of finite-order standard and nonlinear GARCH models, we obtained a surprisingly simple, and easy to estimate, expression for the AREs of the one-step estimator with respect to the two-step QML and LAD estimators.

We suggest a procedure based on a sole Gaussian QML estimation of the model to determine which method should be used. Applied to a set of stock indices, this procedure suggests that the one-step approach should in general be used for moderate values of $r$. Conversely, for predicting $|\varepsilon_t|$ with $r > 2$ or $r < 0.5$, the two-step methods should do a better job. We compared out-of-sample predictions obtained by the proposed adaptive procedure with more elementary approaches. The superiority of the adaptive method appears in a vast majority of cases, whatever the value of $r$.

A natural extension of this work would consider heteroskedastic models including a conditional mean. For instance, Ling (2004) introduced a class of double-autoregressive models and studied the properties of the QMLE, while Audrino and Bühlmann (2009) developed estimation procedures for a non-parametric class. This extension is left for future research.

A. Technical assumptions and proofs

Let $\Delta_t(\theta) = \bar{\sigma}_t(\theta) - \sigma_t(\theta)$, $a_t = \sup_{\theta \in \Theta} |\Delta_t(\theta)|$. Constants $\delta \in \mathbb{R}$ and $C_0 > 0$ refer to Assumption A4. Let $C$ and $\rho$ be generic constants, whose values will be modified along the proofs, such that $C > 0$ and $0 < \rho < 1$. In assumptions A6 and A9 below, $C$ is allowed to be a random variable which is measurable with respect to $\{e_u, u \leq 0\}$.

A6: For any real sequence $(x_i)$, the function $\theta \mapsto \sigma(x_1, x_2, \ldots; \theta)$ is continuous. When $\delta > 0$ we have $E|\alpha_0|^s < \infty$, when $\delta < -1$ we have $E\sup_{\theta \in \Theta} \sigma_0^s(\theta) < \infty$ for some $s > 0$.

We have $a_t \leq C\rho^t$, a.s.

A7: $\theta_0$ belongs to the interior $\Theta$ of $\Theta$.

A8: $h$ is twice differentiable at all $u \in \mathbb{R}^\ast$ with $|u^2 (h'(u)/h(u))'| \leq C_0 (1 + |u|^\delta)$ and $E|\eta_t|^{2\delta} < \infty$.

A9: For any real sequence $(x_i)$, the function $\theta \mapsto \sigma(x_1, x_2, \ldots; \theta)$ has continuous second-order derivatives. There exists a neighborhood $V(\theta_0)$ of $\theta_0$ such that

$$b_t := \sup_{\theta \in V(\theta_0)} \left\| \frac{\partial \Delta_t(\theta)}{\partial \theta} \right\| \leq C\rho^t, \text{ a.s.}$$

A10: The following variables have finite expectation:

$$\sup_{\theta \in V(\theta_0)} \left\| \frac{1}{\bar{\sigma}_t(\theta)} \frac{\partial \bar{\sigma}_t(\theta)}{\partial \theta} \right\|^4, \sup_{\theta \in V(\theta_0)} \left\| \frac{1}{\bar{\sigma}_t(\theta)} \frac{\partial^2 \bar{\sigma}_t(\theta)}{\partial \theta \partial \theta'} \right\|^2, \sup_{\theta \in V(\theta_0)} \left\| \frac{\sigma_t(\theta_0)}{\bar{\sigma}_t(\theta)} \right\|^{2\delta}.$$

Assumptions A6, A9, A10 are satisfied for standard GARCH models and many extensions. In particular, see Francq and Zakoïan (2004) for the bounds in $C_0\rho^t$ for $a_t$ and $b_t$. Assumption A7 is a standard assumption. Assumption A8 reduces to $E|\eta_t|^{2\delta} < \infty$ for instrumental densities of the form $h(u) = K_1 |u|^{\lambda} \exp\{K_2 |u|^\tau\}$, for some constants $\lambda, K_1, K_2$. 

Predictions of powers of ARCH 17
The consistency is a consequence of the following intermediate results:

A.2. Proof of Theorem 2.1

If \( h \in C(r) \) the implication can be obtained by direct verification, for \( r > 0 \), \( r < 0 \) and \( r = 0 \). For the converse, it will be sufficient to consider the case \( r \neq 0 \), the case \( r = 0 \) being treated along the same lines. For \( h \in H_0 \), we will use the convention that \( x h'(x)/h(x) \) is equal to zero at \( x = 0 \). We then have

\[
g_1(x, \sigma) = \frac{\partial g(x, \sigma)}{\partial \sigma} = -\frac{1}{\sigma} \frac{h'(x/\sigma)}{h(x/\sigma)}\frac{x}{\sigma^2}
\]

for \( \sigma > 0 \). Under A4, we have \( E \sup_{x \in V(1)} |g_1(x, \sigma)| < \infty \), for some neighborhood \( V(1) \) of 1. The dominated convergence theorem shows that A3 entails the moment condition

\[
E \left( \frac{h'(\eta)}{h(\eta)} \right) = -1.
\] (19)

The problem is to find \( h \in H_0 \) satisfying (19) for any distribution satisfying A1. The set of all possible densities \( h \) is thus,

\[
H = \left\{ h \in H_0 \mid \text{for any variable } \eta, \ E|\eta|^r = 1 \Rightarrow E \left( \frac{h'(\eta)}{h(\eta)} \right) = -1 \right\}.
\]

We note that this set contains the set

\[
H' = \left\{ h \in H_0 \mid \exists \lambda, \ h'(x) h(x) + 1 = \lambda(|x|^r - 1) \right\}.
\]

Now we prove that \( H \subset H' \). Let \( h \not\in H' \). If \( h'(1)/h(1) \neq -1 \) then \( h \not\in H \) because if \( \eta = 1 \) a.s. then \( E|\eta|^r = 1 \) and \( E h'(\eta)/h(\eta) \neq -1 \). Similarly \( h'(-1)/h(-1) \neq 1 \) entails \( h \not\in H \).

Now consider the case where \( |x_1| > 1, |x_2| < 1 \) and \( \lambda_1 \neq \lambda_2 

\[
h'(x_1)/h(x_1) x_1 + 1 = \lambda_1(|x_1|^r - 1), \quad i = 1, 2.
\]

Let \( \eta \) such that \( P(\eta = x_1) = p_1 > 0 \) with \( p_1 + p_2 = 1 \), and \( (|x_1|^r - 1)p_1 + (|x_2|^r - 1)p_2 = 0 \). Then \( E|\eta|^r = 1 \) and

\[
E \left( \frac{h'(\eta)}{h(\eta)} \right) + 1 = \lambda_1(|x_1|^r - 1)p_1 + \lambda_2(|x_2|^r - 1)p_2 = (\lambda_1 - \lambda_2)(|x_1|^r - 1)p_1 \neq 0.
\]

We thus have \( h \not\in H \). We have proven that \( H = H' \). It remains to verify that \( H = C(r) \) by solving the differential equation involved in the definition of \( H' \), and the proposition follows. \( \square \)

A.2. Proof of Theorem 2.1

The consistency is a consequence of the following intermediate results:

i) \( \lim_{n \to \infty} \sup_{\theta \in \Theta} |Q_n(\theta) - \hat{Q}_n(\theta)| = 0 \), a.s., \( \text{where } Q_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} g(\epsilon_i, \sigma_i(\theta)) \),

ii) if \( \theta \neq \theta_0 \), \( \mathbb{E} g(\epsilon_1, \sigma_1(\theta)) < \mathbb{E} g(\epsilon_1, \sigma_1(\theta_0)) \),

iii) any \( \theta \neq \theta_0 \) has a neighborhood \( V(\theta) \) such that

\[
\lim_{n \to \infty} \sup_{\theta^* \in V(\theta)} \hat{Q}_n(\theta^*) < \lim_{n \to \infty} \hat{Q}_n(\theta_0), \text{ a.s.}
\]
The AN is proven by means of the following intermediate results: for some neighborhood \( V(\theta_0) \) of \( \theta_0 \) and for any \( \theta^* \) between \( \hat{\theta}_{n,h} \) and \( \theta_0 \),

\[
iv) \lim_{n \to \infty} \sqrt{n} \sup_{\theta \in V(\theta_0)} \left| \frac{\partial}{\partial \theta} Q_n(\theta) - \frac{\partial}{\partial \theta} \hat{Q}_n(\theta) \right| = 0, \text{ in probability,}
\]

\[
v) \frac{\partial^2}{\partial \theta \partial \theta} Q_n(\theta^*) \to \frac{E g_2(\eta_0, 1)}{4} f, \text{ in probability,}
\]

\[
vii) \sqrt{n} \frac{\partial}{\partial \theta} Q_n(\theta_0) \xrightarrow{D} \mathcal{N} \left( 0, \frac{E g_2^2(\eta_0, 1)}{4} f \right),
\]

To save space, we only give the proof of \( iv \). This point, as well as \( iv \), which deal with the effect of the initial values, constitute the most delicate parts of the proof and illustrate the necessity of assumptions of the form \( \text{A4, A6 and A9-A10.} \)

Using a Taylor expansion, almost surely

\[
\sup_{\theta \in \Theta} |Q_n(\theta) - \hat{Q}_n(\theta)| \leq n^{-1} \sum_{t=1}^{\infty} \sup_{\theta \in \Theta} |g_t(\theta, \sigma_t^*(\theta))| \left| \Delta_t(\theta) \right|
\]

\[
\leq n^{-1} \sum_{t=1}^{\infty} \alpha_t \sup_{\theta \in \Theta} \left| \frac{1}{\sigma_t^* \sigma_t^*'} \delta \left( \frac{\theta_t}{\sigma_t^*} \right) \right| + \frac{1}{\sqrt{n}} n^{-1} \sum_{t=1}^{\infty} \alpha_t
\]

\[
\leq n^{-1} \sum_{t=1}^{\infty} \alpha_t |\epsilon_t|^\delta \sup_{\theta \in \Theta} \left| \frac{1}{\sigma_t^*} \right| + C \sum_{n=1}^{\infty} \alpha_t
\]

where \( \sigma_t^*(\theta) \) is between \( \hat{\sigma}_t(\theta) \) and \( \sigma_t(\theta) \). The last two inequalities rest on Assumptions \( \text{A4 and A2. \ First suppose } \delta \geq -1. \text{ Then the supremum in (20) is bounded by } C. \text{ If } \delta > 0, \text{ by the Markov inequality and A6, we deduce}
\]

\[
\sum_{t=1}^{\infty} \mathbb{P}(\alpha_t |\epsilon_t|^\delta > \varepsilon) \leq \sum_{t=1}^{\infty} \frac{C \rho^{t/\delta} \mathbb{E}[|\epsilon_t|^\delta]}{\varepsilon^\delta} < \infty
\]

and thus \( \alpha_t |\epsilon_t|^\delta \to 0 \text{ a.s by the Borel-Cantelli lemma. The first term in (20) thus tends to zero a.s., when } \delta > 0, \text{ by the Cesàro lemma. Now, if } \delta \in [-1, 0], \text{ we note that } E|\epsilon_t|^\delta < \infty \text{ by A2 and A4. Note also that, for } s \in (0, 1), \text{ the } c_r \text{ inequality (see Loève, 1977) entails}
\]

\[
\left( n^{-1} \sum_{t=1}^{n} a_t |\epsilon_t|^\delta \right)^s \leq n^{-s/2} \sum_{t=1}^{\infty} C \rho^{t/\delta} |\epsilon_t|^\delta.
\]

The last sum is a.s. finite since its expectation is finite by A6 and \( E|\epsilon_t|^{\delta s} < \infty \) (because \( s \in (0, 1) \)). Hence the first term in (20) tends to zero a.s. when \( \delta \in [-1, 0] \). Now suppose \( \delta < -1 \). Observe that \( \sup_{\theta \in \Theta} \sigma_t^*(\theta) \leq \sup_{\theta \in \Theta} \sigma_t(\theta) + a_t \). It follows that, letting \( \Psi_t = \sup_{\theta \in \Theta} \sigma_t(\theta), \) the first term in (20) can be bounded by

\[
\frac{C}{n} \sum_{t=1}^{n} a_t |\epsilon_t|^\delta \left[ \Psi_t + a_t \right]^{-(1+\delta)} \leq \frac{C}{n} \sum_{t=1}^{n} \rho^t |\eta_t|^{1+\delta} + C \sum_{t=1}^{n} \rho^{-\delta t} |\eta_t|^\delta.
\]

Now by A6, there exists \( s > 0 \) such that

\[
\sum_{t=1}^{\infty} \mathbb{P}(\rho^t |\eta_t|^{1+\delta} > \varepsilon) \leq \sum_{t=1}^{\infty} \left( \frac{\rho^{-t/\delta} \mathbb{E}[|\eta_t|^{1+\delta}]}{\varepsilon} \right)^{1/2} E|\eta_t|^{1+\delta} < \infty.
\]
Thus, the first term in the right-hand side of (21) tends to zero a.s. by the Cesàro Lemma. The second term is treated straightforwardly. We have shown that the first term in the right-hand side of (20) tends to zero a.s. whatever the value of $\delta$. By A6, the second term also tends to zero. Thus $i)$ follows.

A3. Proof of Theorem 3.1

It will be sufficient to derive the advanced results for $r \neq 0$. The same arguments can be used for $r = 0$. Because $E\eta^2 = 1$, the identifiability condition A3, with $\eta$ replaced by $\eta^\circ$, is satisfied when $h$ is the standard Gaussian density. Note also that A4 and A8 hold with $\delta = 2$. Thus, by Theorem 2.1, $\hat{\theta}_n \to \theta^\circ$ a.s. and

$$
\sqrt{n} \left( \hat{\theta}_n - \theta^\circ \right) = -J^{-1}_r \frac{1}{\sqrt{n}} \sum_{t=1}^{n} \left( 1 - \frac{\eta^2}{E\eta^2} \right) \frac{\partial \sigma^2(\theta^\circ)}{\partial \theta} + o_P(1)
$$

$$
\overset{\text{d}}{\to} \mathcal{N}(0, (\kappa_4 - 1)J^{-1}_r).
$$

(22)

Let $\eta_t(\theta) = \epsilon_t \sigma_t^{-1}(\epsilon_{t-1}, \epsilon_{t-2}, \ldots; \theta)$, $\tilde{\eta}_t(\theta) = \epsilon_t \sigma_t^{-1}(\epsilon_{t-1}, \ldots, \epsilon_1, \bar{\epsilon}_0, \bar{\epsilon}_1, \ldots; \theta)$,

$$
\mu_r(\theta) = \frac{1}{n} \sum_{t=1}^{n} |\eta_t(\theta)|^r, \quad \text{for } r \neq 0, \quad \mu_0(\theta) = \frac{1}{n} \sum_{t=1}^{n} \log |\eta_t(\theta)|, \quad \text{for } r = 0.
$$

We similarly define $\tilde{\mu}_r(\theta)$, by replacing $\eta_t(\theta)$ by $\tilde{\eta}_t(\theta)$. By A6, it can be shown that

$$
\hat{\mu}_n \to \tilde{\mu}_n(\theta^\circ) = \mu_r(\theta^\circ) + o_P(n^{-1/2}).
$$

(23)

A Taylor expansion gives

$$
\mu_r(\hat{\theta}_n^\circ) = \mu_r(\theta^\circ) + \frac{\partial \mu_r(\theta^\circ)}{\partial \theta^\circ} (\hat{\theta}_n^\circ - \theta^\circ)
$$

(24)

with $\theta^\circ$ between $\hat{\theta}_n^\circ$ and $\theta^\circ$ and

$$
\left\| \frac{\partial \mu_r(\theta^\circ)}{\partial \theta^\circ} \right\| \leq \frac{K}{n} \sum_{t=1}^{n} |\eta_t(\theta)|^r \sigma_t(\theta^\circ) \left\| \frac{\partial \sigma^2(\theta^\circ)}{\partial \theta^\circ} \right\|.
$$

Using Assumption A10 and the Cauchy-Schwarz inequality, the left hand side has finite expectation. Thus, in view of the consistency of $\hat{\theta}_n^\circ$ to $\theta^\circ$, the last term in (24) converges to 0 a.s. In view of the convergence of $\mu_r(\hat{\theta}_n^\circ)$ to $\mu_r^\circ$, and using (23), the strong consistency of $\hat{\theta}_n^\circ$ follows.

Now, by (22), A10 and standard arguments, a Taylor expansion gives

$$
\mu_r(\hat{\theta}_n^\circ) = \mu_r(\theta^\circ) + \frac{\partial \mu_r(\theta^\circ)}{\partial \theta^\circ} (\hat{\theta}_n^\circ - \theta^\circ) + o_P(n^{-1/2})
$$

(25)

with

$$
\frac{\partial \mu_r(\hat{\theta}_n^\circ)}{\partial \theta^\circ} = -\frac{r}{2n} \sum_{t=1}^{n} |\eta_t(\theta)|^r \frac{1}{\sigma_t^2(\theta^\circ)} \frac{\partial \sigma^2(\theta^\circ)}{\partial \theta^\circ} = -\frac{r}{2} E|\eta_t^2|^r \Omega^\circ + o_P(1).
$$
It follows that
\[
\sqrt{n}(\hat{\mu}^*_r - \mu^*_r) = \sqrt{n}(\mu^*(\theta_0^r) - \mu^*_r) - \frac{r}{2} E|\eta|^r \sqrt{n} \sum_{t=1}^n (\eta^*_t)^r - \frac{r}{2} E|\eta|^r \sqrt{n} (\hat{\theta}^r_n - \theta_0^r) + o_P(1)
\]
\[
= \frac{1}{\sqrt{n}} \sum_{t=1}^n (|\eta|^r - \mu^*_r) - \frac{r}{2} E|\eta|^r \sqrt{n} (\hat{\theta}^r_n - \theta_0^r) + o_P(1)
\]
\[
= \frac{1}{\sqrt{n}} \sum_{t=1}^n (|\eta|^r - 1) - \frac{r}{2} \kappa_r \Omega^r \sqrt{n} (\hat{\theta}^r_n - \theta_0^r) + o_P(1).
\] (26)

Noting that \(\text{Cov}(|\eta|^r, \eta^2) = \mu_{2+\eta}^r (\kappa_{2+r} - \kappa_r)\), we have
\[
\text{Cov} \left( \sqrt{n} \left( \hat{\theta}^r_n - \theta_0^r \right), \frac{1}{\sqrt{n}} \sum_{t=1}^n \frac{|\eta|^r - 1}{\mu_{2+\eta}^r} \right) = (\kappa_{2+r} - \kappa_r) J^{-1} \Omega^r + o_P(1).
\]

It follows from (26) that \(\text{Cov} \left( \sqrt{n} \left( \hat{\theta}^r_n - \theta_0^r \right), \sqrt{n}(\hat{\mu}^*_r - \mu^*_r) \right) = -\lambda_r J^{-1} \Omega^r + o_P(1)\). We also have \(\text{Var}(\sqrt{n}(\hat{\mu}^*_r - \mu^*_r)) = \kappa_{2+r} - \kappa_r^2 + \frac{2}{\sqrt{n}} \{\lambda_r - (\kappa_{2+r} - \kappa_r)\} \Omega^r J^{-1} \Omega^r + o_P(1)\). Finally, the CLT for martingale differences and the Wold-Crèmer device entail (7), provided that (8) holds. Now we prove (8). First note that \(\lambda_2 = 0\). Because \(\mu_{2+\eta}^2 = 1\), the previous expansion writes, when \(r = 2\), \(\text{Var}(\sqrt{n}(\hat{\mu}^*_r - 1)) = (\kappa_4 - 1)(1 - \Omega^r J^{-1} \Omega^r) + o_P(1)\). Note that by B1, for any \(c > 0\), \(c \hat{\sigma}(\hat{\theta}_n^r) = \hat{\sigma}(F(\hat{\theta}_n^r, c))\). Then the maximum of the function \(c \mapsto \hat{Q}_n(F(\hat{\theta}_n^r, c))\), where \(\hat{Q}_n\) is defined in (4) with \(h = \phi\), is uniquely obtained for \(c = \mu_{2+\eta}^2\). Because \(c = 1\) also yields a maximum, by definition of the QMLE, we must have \(\hat{\mu}_{2+\eta}^2 = 1, a.s\). The conclusion follows.}

\section{B. Complementary results}

\subsection{B.1. Proof of Corollary 1}

The direct part is straightforward since we have seen that the QMLE does not depend on the choice of \(h \in \mathcal{C}(r)\).

Now suppose \(f \notin \mathcal{C}(r)\) for \(r \neq 0\). Then, by Cauchy-Schwarz
\[
\frac{\tau^2_{f,f}}{\tau^2_{f,f}} = \text{Var} \left( 1 + \frac{f'(\eta_0)}{f(\eta_0)} \eta_0 \right) \text{Var} \left( \frac{|\eta|^r - 1}{r} \right)
\]
\[
\geq \left\{ \text{Cov} \left( \frac{f'(\eta_0)}{f(\eta_0)}, \frac{|\eta|^r}{r} \right) \right\}^2 = \left\{ E \left( \frac{f'(\eta_0)}{f(\eta_0)} \right) \frac{|\eta|^r}{r} + \frac{1}{r} \right\}^2 = 1
\]
where the last equality is obtained by integration by part. The inequality is strict except if
\[
1 + \frac{f'(\eta_0)}{f(\eta_0)} \eta_0 = K(|\eta|^r - 1), \quad a.s.
\]
for some constant \(K\). The last equality is equivalent to \(f \in \mathcal{C}(r)\), as seen in the proof of Proposition 2. A similar argument holds when \(r = 0\). \(\square\)
B.2. Complementary results for the proof of Theorem 2.1

For the consistency, it remains to show ii) and iii), and for the asymptotic normality it remains to show iv)-vii).

To prove ii), it suffices to use A2-A3 and

\[ g(\epsilon_t, \sigma_t(\theta)) = g\left( \eta_t, \frac{\sigma_t(\theta)}{\sigma_t(\theta_0)} \right) - \log \sigma_t(\theta_0). \]

Indeed, we have

\[ \mathbb{E}\{g(\epsilon_1, \sigma_1(\theta)) - g(\epsilon_1, \sigma_1(\theta_0))\} = \mathbb{E}\left\{ g\left( \eta_t, \frac{\sigma_t(\theta)}{\sigma_t(\theta_0)} \right) - g(\eta_t, 1) \right\} \leq 0, \]

with equality if and only if \( \theta = \theta_0 \).

Now we will show iii). For any \( \theta \in \Theta \) and any positive integer \( k \), let \( V_k(\theta) \) be the open ball with center \( \theta \) and radius \( 1/k \). We have,

\[
\lim_{n \to \infty} \sup_{\theta^* \in V_k(\theta) \cap \Theta} \tilde{Q}_n(\theta^*) \\
\leq \lim_{n \to \infty} \sup_{\theta^* \in V_k(\theta) \cap \Theta} Q_n(\theta^*) + \lim_{n \to \infty} \sup_{\theta \in \Theta} |Q_n(\theta) - \tilde{Q}_n(\theta)| \\
\leq \lim_{n \to \infty} n^{-1} \sum_{t=1}^{n} \sup_{\theta^* \in V_k(\theta) \cap \Theta} g(\epsilon_t, \sigma_t(\theta^*)) \quad \text{a.s.}
\]

where the second inequality comes from i). Note that since \( h \) is integrable and differentiable, \( h \) is bounded. It follows, by A2, that

\[
\mathbb{E} \sup_{\theta^* \in V_k(\theta) \cap \Theta} g(\epsilon_t, \sigma_t(\theta^*)) < \log \frac{1}{\omega} + C < \infty. \quad (27)
\]

Using an ergodic theorem for stationary and ergodic processes \((X_t)\) such that \( \mathbb{E}(X_t) \) exists in \( \mathbb{R} \cup \{-\infty, +\infty\} \) (see Billingsley, 1995, p. 284 and 495), it follows that

\[
\lim_{n \to \infty} \sup_{\theta^* \in V_k(\theta) \cap \Theta} \tilde{Q}_n(\theta^*) \leq \mathbb{E}X_{t,k}(\theta), \quad X_{t,k}(\theta) = \sup_{\theta^* \in V_k(\theta) \cap \Theta} g(\epsilon_t, \sigma_t(\theta^*)).
\]

When \( k \) tends to infinity, the sequence \( \{X_{t,k}(\theta)\}_k \) decreases to \( X_t(\theta) = q(\epsilon_t, \sigma_t(\theta)) \). Thus \( \{X_{t,k}(\theta)\}_k \) increases to \( X_t^-(\theta) \). By the Beppo-Levi theorem, \( \mathbb{E}X_{t,k}^-(\theta) \uparrow \mathbb{E}_\theta X_t^-(\theta) \) when \( k \uparrow +\infty \). By \( (27) \), the fact that the sequence \( \{X_{t,k}^+(\theta)\}_k \) is decreasing, and the Lebesgue theorem, \( \mathbb{E}X_{t,k}^+(\theta) \downarrow \mathbb{E}X_t^+(\theta) \) when \( k \uparrow +\infty \). Thus we have shown that \( \mathbb{E}X_{t,k} \) converges to \( \mathbb{E}\{X_t(\theta)\} \) when \( k \to \infty \). By ii), iii) is proved.

As in the proof of Theorem 2.1 in Francq and Zakoian (2004), the consistency is a consequence of a standard compactness argument and of the intermediate results i)-iii).

Now we prove iv). We have

\[
\frac{\partial}{\partial \theta} Q_n(\theta) = \frac{1}{n} \sum_{t=1}^{n} g_1(\epsilon_t, \sigma_t(\theta)) \frac{\partial \sigma_t(\theta)}{\partial \theta} , \quad \frac{\partial}{\partial \theta} \tilde{Q}_n(\theta) = \frac{1}{n} \sum_{t=1}^{n} g_1(\epsilon_t, \tilde{\sigma}_t(\theta)) \frac{\partial \tilde{\sigma}_t(\theta)}{\partial \theta}.
\]
It follows that
\[
\sup_{\theta \in V(\theta_0)} \sqrt{n} \left\| \frac{\partial}{\partial \theta} Q_n(\theta) - \frac{\partial}{\partial \theta} \tilde{Q}_n(\theta) \right\|
\leq \sup_{\theta \in V(\theta_0)} \frac{1}{\sqrt{n}} \sum_{t=1}^{n} |g_1(\epsilon_t, \sigma_t(\theta)) - g_1(\epsilon_t, \tilde{\sigma}_t(\theta))| \left\| \frac{\partial \sigma_t(\theta)}{\partial \theta} \right\| + \sup_{\theta \in V(\theta_0)} \frac{1}{\sqrt{n}} \sum_{t=1}^{n} |g_1(\epsilon_t, \tilde{\sigma}_t(\theta))| \left\| \frac{\partial \tilde{\sigma}_t(\theta)}{\partial \theta} \right\|.
\]

(28)

Similarly to (20), the last term is bounded on $V$ by
\[
\frac{C}{\sqrt{n}} \sum_{t=1}^{n} b_t \left\{ |\epsilon_t|^{\delta} \sup_{\theta \in V(\theta_0)} \left| \frac{1}{\tilde{\sigma}_t(\theta)} \right| \right\}^{1+\delta} + 1 \leq \frac{C}{\sqrt{n}} \sum_{t=1}^{n} b_t |\eta_t|^\delta \sup_{\theta \in V(\theta_0)} \left| \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right|^\delta + C \frac{1}{\sqrt{n}} \sum_{t=1}^{n} b_t.
\]

(29)

We will prove that there exists $s > 0$ such that
\[
\sup_{t} E \sup_{\theta \in V(\theta_0)} \left( \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right)^{\delta s} < \infty.
\]

(30)

A Taylor expansion gives, for $\sigma^*_t(\theta)$ between $\sigma_t(\theta_0)$ and $\tilde{\sigma}_t(\theta)$,
\[
\left\{ \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right\}^{\delta s} = \left\{ \frac{\sigma_t(\theta_0)}{\sigma_t(\theta)} \right\}^{\delta s} - 2\delta s \Delta_t(\theta) \left\{ \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right\}^{\delta s} \left\{ \frac{1}{\sigma_t(\theta)} \right\}^{\delta s+1} \leq \left\{ \frac{\sigma_t(\theta_0)}{\sigma_t(\theta)} \right\}^{\delta s} + C \rho^s \left\{ \sigma_t(\theta_0) \right\}^{\delta s}
\]

since $\delta s > 0$ for $s$ small enough. The first term in the right-hand side admits a finite expectation when $s \leq 2$ using A10. The second term admits a finite expectation, hence (30) is proved.

We have $E |\eta_t|^{\delta s} < \infty$ for $s \in (0, 1)$. Therefore, by (30),
\[
E \left( \sum_{t=1}^{\infty} \rho^s/2 |\eta_t|^{\delta s/2} \sup_{\theta \in V(\theta_0)} \left| \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right|^{\delta s/2} \right) < \infty
\]

and thus the random variable inside the bracket is a.s. finite. It follows that
\[
\left( n^{-1/2} \sum_{t=1}^{n} b_t |\eta_t|^\delta \sup_{\theta \in V(\theta_0)} \left| \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right|^\delta \right)^{s/2} \leq n^{-s/4} C \sum_{t=1}^{\infty} \rho^s/2 |\eta_t|^{\delta s/2} \sup_{\theta \in V(\theta_0)} \left| \frac{\sigma_t(\theta_0)}{\tilde{\sigma}_t(\theta)} \right|^{\delta s/2} \to 0
\]

which shows that the first term in the right-hand side of (29) goes to zero a.s. as $n$ tends to infinity. The second term is handled in a straightforward way. Thus the last term in (28)
converges to zero a.s. as \( n \) tends to infinity. Now note that
\[
g_2(x, \sigma) := \frac{\partial g_1(x, \sigma)}{\partial \sigma} = \frac{1}{\sigma^2} \left[ 1 + 1_{\{x \neq 0\}} \frac{x}{\sigma} \left( 2 \frac{h'}{h} + \frac{x}{\sigma} \left( \frac{h'}{h} \right) \right) \left( \frac{x}{\sigma} \right) \right]. \quad (31)
\]

From A4 and A8, the first term in the right-hand side of (28) is bounded by
\[
\sup_{\theta \in V(\theta_0)} \frac{1}{\sqrt{n}} \sum_{t=1}^{n} \left| g_2(\epsilon_t, \sigma_t^*) \right| |\Delta_t(\theta)| \left\| \frac{\partial \sigma_t(\theta)}{\partial \theta} \right\| \leq \frac{C}{\sqrt{n}} \sum_{t=1}^{n} a_t \left( 1 + |\epsilon_t| \delta \sup_{\theta \in V(\theta_0)} \left| \frac{1}{\sigma_t^*} \right|^{2+\delta} \right) \sup_{\theta \in V(\theta_0)} \left\| \frac{1}{\sigma_t(\theta)} \frac{\partial \sigma_t(\theta)}{\partial \theta} \right\| \quad (32)
\]
where \( \sigma_t^* = \sigma_t^*(\theta) \) is between \( \tilde{\sigma}_t(\theta) \) and \( \sigma_t(\theta) \). For \( \delta > 0 \) there exists \( s \in (0, 2\delta) \) such that, by the \( c_r \) and Cauchy-Schwarz inequalities,

\[
E \left( \sum_{t=1}^{\infty} a_t (1 + |\epsilon_t|^\delta) \sup_{\theta \in V(\theta_0)} \left| \frac{1}{\sigma_t(\theta)} \frac{\partial \sigma_t(\theta)}{\partial \theta} \right| \right)^{s/2} 
\leq \sum_{t=1}^{\infty} \rho_t^{s/2} \left\{ E (1 + |\epsilon_0|^s) \right\}^{1/2} \left\{ E \left( \sup_{\theta \in V(\theta_0)} \left| \frac{1}{\sigma_0(\theta)} \frac{\partial \sigma_0(\theta)}{\partial \theta} \right| \right)^s \right\}^{1/2} < \infty
\]
by A6 and A10. For \( \delta \in [-1, 0] \) and \( s \in (0, 1) \) we have, similarly, using \( E|\epsilon_0|^\delta \leq \Omega^\delta E|\eta_0|^\delta \),

\[
E \left( \sum_{t=1}^{\infty} a_t (1 + |\epsilon_t|^\delta) \sup_{\theta \in V(\theta_0)} \left| \frac{1}{\sigma_t(\theta)} \frac{\partial \sigma_t(\theta)}{\partial \theta} \right| \right)^{s/2} 
\leq \sum_{t=1}^{\infty} \rho_t^{s/2} \left\{ E (1 + |\epsilon_0|^s) \right\}^{1/2} \left\{ E \left( \sup_{\theta \in V(\theta_0)} \left| \frac{1}{\sigma_0(\theta)} \frac{\partial \sigma_0(\theta)}{\partial \theta} \right| \right)^s \right\}^{1/2} < \infty.
\]
The case \( \delta < -1 \) is treated in the same fashion, using an inequality similar to (21). By arguments already used, we conclude that the first term in the right-hand side of (28) goes to zero a.s. as \( n \) tends to infinity. Thus \( iv) \) is established. The invertibility of \( J \) follows from A5.

Now we establish \( v) \). In view of A4 and A8, we have
\[
\left\| \frac{\partial^2 Q_n(\theta)}{\partial \theta \partial \theta'} \right\| = \left\| \frac{1}{n} \sum_{t=1}^{n} \frac{\partial^2 g(\epsilon_t, \sigma_t(\theta))}{\partial \theta \partial \theta'} \right\|
\leq \left\| \frac{1}{n} \sum_{t=1}^{n} g_2(\epsilon_t, \sigma_t(\theta)) \frac{\partial \sigma_t(\theta)}{\partial \theta} \frac{\partial \sigma_t(\theta)}{\partial \theta'} + g_1(\epsilon_t, \sigma_t(\theta)) \frac{\partial^2 \sigma_t(\theta)}{\partial \theta \partial \theta'} \right\|
\leq \frac{C}{n} \sum_{t=1}^{n} \left( 1 + \left| \frac{\sigma_t(\theta_0) \eta_t}{\sigma_t(\theta)} \right|^{\delta} \right) \left( \left\| \frac{1}{\sigma_t(\theta)} \frac{\partial \sigma_t(\theta)}{\partial \theta} \right\| \left\| \frac{\partial^2 \sigma_t(\theta)}{\partial \theta \partial \theta'} \right\| + \left\| \frac{1}{\sigma_t^*(\theta)} \frac{\partial \sigma_t^*(\theta)}{\partial \theta} \frac{\partial \sigma_t(\theta)}{\partial \theta'} \right\| \right).
\]
Predictions of powers of ARCH

Hence

\[ E \sup_{\theta \in V(\theta_0)} \left\| \frac{\partial^2 Q_n(\theta)}{\partial \theta \partial \theta'} \right\| \leq C \]

by the Hölder inequality, A8 and A10. The ergodic theorem then implies that

\[ \lim_{n \to \infty} \sup_{\theta \in V(\theta_0)} \left\| \frac{\partial^2 Q_n(\theta)}{\partial \theta \partial \theta'} - \frac{\partial^2 Q_n(\theta_0)}{\partial \theta \partial \theta'} \right\| \leq E \sup_{\theta \in V(\theta_0)} \left\| \frac{\partial^2 g(\epsilon_t, \sigma_t(\theta))}{\partial \theta \partial \theta'} - \frac{\partial^2 g(\epsilon_t, \sigma_t(\theta_0))}{\partial \theta \partial \theta'} \right\|, \text{ a.s.} \]

By the dominated convergence theorem, the last expectation tends to zero when the neighborhood \( V(\theta_0) \) tends to the singleton \{\theta_0\}. The consistency of \( \hat{\theta}_{n,h} \) thus entails

\[ \lim_{n \to \infty} \left\| \frac{\partial^2 Q_n(\theta^*)}{\partial \theta \partial \theta'} - \frac{\partial^2 Q_n(\theta_0)}{\partial \theta \partial \theta'} \right\| = 0, \text{ a.s.} \]

In view of (19),

\[ E g_1(\epsilon_t, \sigma_t(\theta_0)) \frac{\partial^2 \sigma_t(\theta_0)}{\partial \theta \partial \theta'} = 0 \]

and by (31), \( g_2(\epsilon_t, \sigma_t(\theta_0)) = g_2(\eta_t, 1) \sigma_t^{-2}(\theta_0) \). By the ergodic theorem

\[ \lim_{n \to \infty} \frac{\partial^2 Q_n(\theta_0)}{\partial \theta \partial \theta'} = \frac{E g_2(\eta_t, 1)}{4} J, \text{ a.s.} \]

and \( v) \) is established.

To prove \( vi) \) it suffices to note that

\[ \sqrt{n} \frac{\partial}{\partial \theta} Q_n(\theta_0) = \frac{1}{\sqrt{n}} \sum_{t=1}^{n} g_1(\eta_t, 1) \frac{1}{2\sigma_t^2(\theta_0)} \frac{\partial \sigma_t^2(\theta_0)}{\partial \theta} \]

and to apply a CLT for square integrable stationary martingale differences (see Billingsley (1961)).

Now, from A7 and the consistency of \( \hat{\theta}_{n,h} \), a Taylor expansion yields

\[ 0 = \sqrt{n} \frac{\partial}{\partial \theta} Q_n(\hat{\theta}_{n,h}) + \sqrt{n} \frac{\partial}{\partial \theta} Q_n(\hat{\theta}_{n,h}) - \sqrt{n} \frac{\partial}{\partial \theta} Q_n(\hat{\theta}_{n,h}) = \sqrt{n} \frac{\partial}{\partial \theta} Q_n(\theta_0) + \frac{\partial^2}{\partial \theta \partial \theta'} Q_n(\theta^*) \sqrt{n}(\hat{\theta}_{n,h} - \theta_0) \]

where \( \theta^* \) is between \( \hat{\theta}_{n,h} \) and \( \theta_0 \). Applying \( iv), v), vi) \), the proof of the asymptotic normality is complete.
Since, almost surely, \( \theta \) the ergodic theorem, the Cauchy-Schwarz inequality and \( A10 \), we have

\[
|\hat{\mu}_r(\theta) - \mu_r(\theta)| \leq \frac{1}{n} \sum_{t=1}^{n} |\epsilon_t| \frac{|\Delta_t(\theta)|}{\sigma_t(\theta)\sigma_t(\theta)} \\
\leq \frac{1}{n^{\omega/2}} \sum_{t=1}^{n} a_t |\epsilon_t| \leq C \frac{\sum_{t=1}^{\infty} \rho^t |\epsilon_t|}{n}.
\]

By \( A6 \), \( E|\epsilon_t|^s \leq \infty \) for some \( s \in (0,1) \). By the \( c_s \)-inequality, \( E(\sum_{t=1}^{\infty} \rho^t |\epsilon_t|)^s \leq \sum_{t=1}^{\infty} \rho^t E|\epsilon_t|^s \leq \infty \). It follows that

\[
\sup_{\theta \in \Theta} |\hat{\mu}_r(\theta) - \mu_r(\theta)| = O(1/n) \text{ a.s.}
\]

which is a stronger result than (23).

Proof of (25): A Taylor expansion yields

\[
\mu_r(\hat{\theta}_n^*) = \mu_r(\theta_0^*) + \frac{\partial \mu_r(\theta_0^*)}{\partial \theta} (\hat{\theta}_n^* - \theta_0^*) + \frac{1}{2} (\hat{\theta}_n^* - \theta_0^*) \cdot \frac{\partial^2 \mu_r(\theta^*)}{\partial \theta^2} (\hat{\theta}_n^* - \theta_0^*)
\]

where \( \theta^* \) is between \( \hat{\theta}_n^* \) and \( \theta_0^* \) and

\[
\frac{\partial \mu_r(\theta)}{\partial \theta} = -\frac{r}{2n} \sum_{t=1}^{n} |\eta_t(\theta)|^r \cdot \frac{1}{\sigma_t^2(\theta)} \frac{\partial \sigma_t^2(\theta)}{\partial \theta}
\]

\[
\frac{\partial^2 \mu_r(\theta)}{\partial \theta \partial \theta^r} = \left( \frac{r}{2} + \frac{r^2}{4} \right) \frac{1}{n} \sum_{t=1}^{n} |\eta_t(\theta)|^r \cdot \frac{1}{\sigma_t^2(\theta)} \frac{\partial \sigma_t^2(\theta)}{\partial \theta} \frac{\partial \sigma_t^2(\theta)}{\partial \theta^r}
\]

Since

\[
|\eta_t(\theta)|^{2r} = \frac{\sigma_t^{2r}(\theta_0)}{\sigma_t^2(\theta)} |\eta_t|^2
\]

the ergodic theorem, the Cauchy-Schwarz inequality and \( A10 \) show that

\[
\lim_{n \to \infty} \sup_{\theta \in V(\theta_0)} \left| \frac{\partial^2 \mu_r(\theta)}{\partial \theta \partial \theta^r} \right| < \infty.
\]

Since, almost surely, \( \theta^* \in V(\theta_0) \) for \( n \) large enough, we have

\[
\lim_{n \to \infty} \left| \frac{\partial^2 \mu_r(\theta^*)}{\partial \theta \partial \theta^r} \right| = O_P(1).
\]

Noting that, in view of (22), we have \( \hat{\theta}_n^* - \theta_0^* = O_P(n^{-1/2}) \), we obtain

\[
\mu_r(\hat{\theta}_n^*) = \mu_r(\theta_0^*) + \frac{\partial \mu_r(\theta_0^*)}{\partial \theta} (\hat{\theta}_n^* - \theta_0^*) + O_P(n^{-1}),
\]

which implies (25).
B.4. Complementary results for the standard GARCH

Proof of Theorem 3.2. To prove (11) we note that Assumptions A4 and A8 are satisfied with \( \delta = r \). Assumptions A6 and A9 are satisfied because the strict stationarity implies the existence of a moment of order \( s \), for some \( s > 0 \) (see Berkes et al (2003), Lemma 2.3), and by Equations (4.6) and (4.33) in Francq and Zako\'ien (2004). The latter paper also established the second part of A2 and A10. The convergence (11) follows from Theorem 2.1.

The expression of the two-step estimator \( \hat{\theta}_n \) follows from (5). The convergence in distribution (12) follows from Theorem 3.1. Let \( \Gamma_r \) denote the asymptotic variance in (12). To derive an explicit expression for \( \Gamma_r \) we use (9) and the following calculations. Denote by \( L \) the lag operator. The derivatives of \( \sigma_t^2(\theta) \) verify

\[
B_\theta(L) \frac{\partial \sigma_t^2(\theta)}{\partial \omega}(\theta) = 1, \quad B_\theta(L) \frac{\partial \sigma_t^2(\theta)}{\partial \gamma_j}(\theta) = \epsilon_t^2, \quad i = 1, \ldots, q, \\
B_\theta(L) \frac{\partial \sigma_t^2(\theta)}{\partial \beta_j}(\theta) = \sigma_{t-j}^2(\theta), \quad j = 1, \ldots, p.
\]

(33)

In view of (5), \( B_\theta(L) = B_\theta(L) \). Moreover \( \sigma_{t-j}^2(\theta_0) = \mu_2 \sigma_{t-j}^2(\theta_0) \). Thus

\[
\frac{\partial \sigma_t^2(\theta_0)}{\partial \theta} = A \frac{\partial \sigma_t^2(\theta_0)}{\partial \theta}, \quad A = \left( \begin{array}{cc} I_{q+1} & 0 \\ 0 & \mu_2 I_p \end{array} \right).
\]

(34)

It follows that

\[
J_* = \mu_2^{-2} A J A, \quad \Omega_* = \mu_2^{-1} A \Omega.
\]

(35)

where \( \Omega = E \left( \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2(\theta_0)}{\partial \theta} \right) \). Hence, the asymptotic variance of Theorem 3.1 is given by

\[
\Sigma_r = \left( \begin{array}{cc} (\lambda_1 - 1) \lambda_2 J^{-1} - \lambda_2 & -\lambda_2 \lambda_3 J^{-1} \\ -\lambda_3 & \lambda_3 \end{array} \right) - \lambda_3 \lambda_4 J^{-1} \Omega.
\]

(36)

Moreover, in view of \( G_r(\theta_0, \mu_r^*) = (\mu_r)_{R}^{2/r} \omega_0^*, \ldots, (\mu_r)_{R}^{2/r} \beta_0^*, \ldots, \beta_{0p}^* \) we have

\[
\left[ \frac{\partial G_r(\theta_0, \mu_r^*)}{\partial \theta^i} \right] = \left[ \begin{array}{c} 1 \mu_2 J^{-1} \Omega \omega_0^* \\ 2 \mu_2 J^{-1} \Omega \beta_0^* \end{array} \right].
\]

(37)

Hence the asymptotic variance of the reparameterized QMLE of the two-step approach

\[
\Gamma_r = (\lambda_1 - 1) J^{-1} - \lambda_2 \mu_2^2 \left( \omega_0^* \Omega' J^{-1} \omega_0^* + \Omega' \Omega \right) + \sigma_r^2 \left( \frac{2 \mu_2^2}{\mu_2} \right)^2 \omega_0^* \omega_0^*.
\]

Now we will show that

\[
J^{-1} \Omega = \omega_0, \quad \Omega' J^{-1} \Omega = 1
\]

(38)

The second equality follows from (35) and (8) but we give a direct proof. In view of (33), we have

\[
B_\theta(L) \frac{\partial \sigma_t^2(\theta)}{\partial \theta} \theta_t^{1+q} \omega_t^{1+q} = \omega + \sum_{i=1}^q \alpha_i \epsilon_{t-i} \sigma_t^2(\theta).
\]
Because, by assumption C and the positivity of the \( \beta_j \), the roots of the polynomial \( \mathcal{B}_\theta(L) \) are outside the unit circle, it follows that

\[
\frac{\partial \sigma_r^2(\theta_0)}{\partial \theta^{1,q+1}} \theta_0^{1,q+1} = \frac{\partial \sigma_r^2(\theta_0)}{\partial \theta^r} \mathbf{v}_0 = \sigma_r^*(\theta_0),
\]

(39)

The first equality in (38) follows. We also have \( \Omega^T \mathbf{v}_0 = 1 \). The second equality in (38) follows. Because \( \mu_2/2 = 1/\kappa_r \), we thus have, by (38)

\[
\Gamma_r = (\kappa_4 - 1)J^{-1} + \left[ \frac{\sigma_r^2}{\mu_r^2} \left( \frac{2}{r \kappa_r} \right)^2 - \frac{4}{r \kappa_r} \lambda_r \right] \mathbf{v}_0 \mathbf{v}_0^T
\]

\[
= (\kappa_4 - 1)J^{-1} + \left( \frac{2}{r \kappa_r} \right)^2 \left[ \kappa_2r - \kappa_r^2 + \frac{r}{2} \kappa_r (\lambda_r - \kappa_2 + \kappa_r) - r \kappa_r \lambda_r \right] \mathbf{v}_0 \mathbf{v}_0^T
\]

\[
= (\kappa_4 - 1)J^{-1} + \left( \frac{2}{r \kappa_r} \right)^2 \left[ \kappa_2r - \kappa_r^2 - \frac{r}{2} \kappa_r \left\{ \frac{r}{2} \kappa_4 - 1 \right\} \right] \mathbf{v}_0 \mathbf{v}_0^T,
\]

which completes the proof of (12). The theorem is established.

\[\square\]

**Theorem B.1 (Standard GARCH\((p,q)\) when \( r = 0 \)).** For \( h \in \mathcal{C}(0) \), \( E \log |\eta_0| = 0 \), \( E \log^2 |\eta_0| < \infty \) and under C, the one-step estimator of \( \theta_0 \in \hat{\Theta} \) satisfies

\[
\sqrt{n} \left( \hat{\theta}_{n,h} - \theta_0 \right) \xrightarrow{\mathcal{L}} \mathcal{N} \left\{ 0, 4 \text{Var} \left[ \log |\eta_0| \right] J^{-1} \right\}.
\]

(40)

Under the same assumptions and \( E \eta_0^4 < \infty \), the two-step estimator is given by \( \hat{\theta}_n = (e^{2\beta_0^* \hat{\omega}_0^*}, e^{2\beta_1^* \hat{\alpha}_1^*}, \ldots, e^{2\beta_0^* \hat{\alpha}_q^*}, \hat{\beta}_1^*, \ldots, \hat{\beta}_p^*) \) and satisfies

\[
\sqrt{n} \left( \hat{\theta}_n - \theta_0 \right) \xrightarrow{\mathcal{L}} \mathcal{N} \left\{ 0, (\kappa_4 - 1)J^{-1} + [4 \text{Var} \left[ \log |\eta_0| \right] - (\kappa_4 - 1)] \mathbf{v}_0 \mathbf{v}_0^T \right\}.
\]

(41)

**Proof.** We note that (40) does not straightforwardly follow from Theorem 2.1 because Assumptions A4 and A8 are not satisfied when \( r = 0 \) and \( h \in \mathcal{C}(0) \). However, tedious computation shows that the conclusion of Theorem 2.1 continues to hold under the assumptions of Theorem B.1.

To prove (41), we use the following expansion, similar to (26),

\[
\sqrt{n}(\hat{\mu}_0^* - \mu_0^*) = \frac{1}{\sqrt{n}} \sum_{r=1}^{n} \left( \log |\eta_r| - E \log |\eta_r| \right) - \frac{1}{2} \Omega_0^* \sqrt{n}(\hat{\theta}_n^* - \theta_0^*) + o_P(1).
\]

Moreover, observe that

\[
\left[ \frac{\partial G_0(\theta_0^*, \mu_0^*)}{\partial (\theta^r, \mu^r)} \right] = \left[ \frac{1}{\mu_2} A 2\mathbf{v}_0 \right].
\]

The conclusion follows along the same lines as in the proof of Theorem 3.2.

\[\square\]

The link between Theorems 3.2 and B.1 is given by the following result, showing the continuity at \( r = 0 \) of the limiting distribution of the two estimators \( \hat{\theta}_n \) and \( \hat{\theta}_{n,h} \).
Proposition 3 (Continuity of the asymptotic variance at \( r = 0 \)). Let \( U \) denote a fixed variable (that is independent of \( r \)) and assume that

\[
\eta_0 \overset{d}{=} \frac{U}{(E|U|^r)^{1/r}}.
\]

Then, under the assumptions of Theorems 3.2 and B.1, we have

\[
\lim_{r \to 0} \left( 2 \right)^2 \left( \frac{\kappa_{2r}}{\kappa_r^2} - 1 \right) = 4 \text{Var}(\log |\eta_0|).
\]

Proof. Note that \( EU^4 < \infty \) and \( E(\log |U|)^2 < \infty \). Let \( f(r) = E(|U|^r \log |U|) \) and \( f''(r) = E(|U|^r \{ \log |U| \}^2) \) for \( r \) small enough. Hence

\[
E|U|^r = 1 + r E(\log |U|) + \frac{r^2}{2} E(\{ \log |U| \}^2) + o(r^2).
\]

Thus

\[
E|U|^{2r} - (E|U|^r)^2 = r^2 \text{Var}(\log |U|) + o(r^2).
\]

Because

\[
\frac{\kappa_{2r}}{\kappa_r^2} - 1 = \frac{E|U|^{2r}}{(E|U|^r)^2} - 1,
\]

the result straightforwardly follows. \( \square \)

The following is the analogue of Corollary 2 for the case \( r = 0 \).

Corollary 3 (A criterion for efficiency comparison when \( r = 0 \)). Under the assumptions of Theorem B.1, the asymptotic variance matrices of the two estimators verify

\[
\text{Var}_as \left\{ \sqrt{n} \left( \hat{\theta}_{n,h} - \theta_0 \right) \right\} \succeq \text{Var}_as \left\{ \sqrt{n} \left( \hat{\theta}_n - \theta_0 \right) \right\}
\]

(42)

in the sense of positive semi-definite matrices, if and only if

\[
4 \text{Var}(\log |\eta_0|) \geq \kappa_4 - 1.
\]

(43)

Proof of Corollaries 2 and 3. It follows from Theorem 3.2 that, for \( r \neq 0 \),

\[
\text{Var}_as \left\{ \sqrt{n} \left( \hat{\theta}_{n,h} - \theta_0 \right) \right\} - \text{Var}_as \left\{ \sqrt{n} \left( \hat{\theta}_n - \theta_0 \right) \right\} = \left[ \left( \frac{2}{r} \right)^2 \left( \frac{\kappa_{2r}}{\kappa_r^2} - 1 \right) - (\kappa_4 - 1) \right] (J^{-1} - \theta_0 \theta_0')
\]

A similar result holds for \( r = 0 \), by Theorem B.1. It remains to show that

\[
J^{-1} \succeq \theta_0 \theta_0'.
\]

(44)

In view of (39),

\[
\theta_0 J = E(Z_t), \quad Z_t = \frac{1}{\sigma_t^2(\theta_0)} \frac{\partial \sigma_t^2(\theta_0)}{\partial \theta}.
\]
Thus $J - J_{00}0 J = \text{Var}(Z_j)$ is positive semi-definite. It follows that
\[
y'(J^{-1} - \theta_0^00 )J y = y'(J - J_{00}0 J)y \geq 0, \quad \forall y \in \mathbb{R}^{q+1}, y \neq 0.
\]
Setting $x = J y$, we thus have
\[
x'(J^{-1} - \theta_0^00 )x \geq 0, \quad \forall x \in \mathbb{R}^{q+1}, x \neq 0
\]
and (44) is proven. \( \square \)

Note that (44) has interest beyond the proof. In particular, it can be used to obtain a
simple lower bound for the asymptotic variance of the generalized QMLE.

B.5. Complementary results for the LAD estimation

We start by proving the following result, giving the joint asymptotic distribution of the
assumptions of Theorem 4.1,
\[
\hat{\beta}_{00} J_{00}0 \text{ and } \hat{\omega}_{00} \end{equation}
\]

Proof.

Proceeding as in the proof of Theorem 2.1, to prove the strong consistency of
\[
\eta = \begin{cases} 1 & \text{if } |\eta_r| > M, \\ 0 & \text{otherwise} \end{cases}
\]

Thus
\[
J_{00}0 \text{ and } \hat{\omega}_{00} \end{equation}
\]

Note that (44) has interest beyond the proof. In particular, it can be used to obtain a
simple lower bound for the asymptotic variance of the generalized QMLE.

B.5. Complementary results for the LAD estimation

We start by proving the following result, giving the joint asymptotic distribution of the
LAD estimation of the criterion defined in (15), we have
\[
\left( \begin{array}{c} \xi \n \end{array} \right) \sim N(0, \Sigma^*_r),
\]

where
\[
\Sigma^*_r = \begin{pmatrix} \sigma^2_r & J_{00}0^{-1} \xi \n \ \xi \end{pmatrix},
\]

and
\[
a_r = \frac{\xi \n \n}{r^{1/2}} \left\{ 2 \xi \sigma^2_r + \delta_r \right\}, \quad \delta_r = E(|\eta_r| \eta_r > M) - E(|\eta_r| \eta_r < M),
\]

\[
\sigma^2_r = \frac{1}{M} \left\{ E(|\eta_r|^2 - 1 + r \xi \sigma^2_r + \delta_r) \right\}.
\]

When $r = 0$, under the assumptions of Theorem B.1, the previous results hold with
\[
a_0 = \xi \sigma^2_r + \delta_0, \quad \delta_0 = E(\log |\eta_0| \eta_2 > M) - E(\log |\eta_0| \eta_2 < M),
\]

\[
\sigma^2_r = \text{Var}(\log |\eta_0|) + \xi \sigma^2_r + \delta_0.
\]

Proof. Proceeding as in the proof of Theorem 2.1, to prove the strong consistency of $\hat{\beta}_{00}^*$
we check the intermediate results

\begin{itemize}
  \item [i)] $\lim_{n \to \infty} \sup_{\theta \in \Theta} |Q_n(\theta) - \hat{Q}_n(\theta)| = 0$, \ a.s.
  \item [ii)] if $\theta \neq 0$, \ $E|\log \epsilon^2 - \log \sigma^2_r(\theta)| < \sup_{\theta \in \Theta} |\log \epsilon^2 - \log \sigma^2_r(\theta)|$
  \item [iii)] any $\theta \neq 0$ has a neighborhood $V(\theta)$ such that
\end{itemize}
with
\[
\hat{Q}_n(\theta) = \frac{1}{n} \sum_{t=1}^{n} |\log \epsilon_t^2 - \log \hat{\sigma}_t^2(\theta)|,
\]
\[
Q_n(\theta) = \frac{1}{n} \sum_{t=1}^{n} |\log \epsilon_t^2 - \log \sigma_t^2(\theta)|.
\]
We have, using the elementary inequality \(||z - y|| - |z|| \leq |y|| and already used arguments,
\[
\sup_{\theta \in \Theta} |Q_n(\theta) - \hat{Q}_n(\theta)| \leq \frac{1}{n} \sum_{t=1}^{n} \sup_{\theta \in \Theta} |\log \sigma_t^2(\theta) - \log \hat{\sigma}_t^2(\theta)| \leq \frac{1}{n} \sum_{t=1}^{n} C \rho' \leq C \frac{1}{n},
\]
which proves i). Now for \(z \neq 0,\)
\[
|z - y| - |z| = -y \text{sgn}(z) + 2(y - z)(\mathbf{1}_{0 < z < y} - \mathbf{1}_{y < z < 0}) \geq -y \text{sgn}(z)
\]
with equality only if \(y = z.\) Hence, for any \(\sigma > 0,\)
\[
E|\log |\eta_0^*|| - \log \sigma| - E|\log |\eta_0^*|| \geq -(\log \sigma)E\{\text{sgn}(\log |\eta_0^*|)\} = 0,
\]
the inequality being strict unless if \(\sigma = 1,\) the equality following from the fact that \(\text{median}(|\eta_0^*|) = 1.\)

Hence, for any \(\sigma > 0,\)
\[
E|\log |\eta_0^*|| - \log \sigma| - E|\log |\eta_0^*|| \geq -(\log \sigma)E\{\text{sgn}(\log |\eta_0^*|)\} = 0,
\]
the equality following from the fact that \(\text{median}(|\eta_0^*|) = 1.\) Now we show that the inequality is strict whence \(\sigma \neq 1.\) For instance, let \(\sigma > 1\) and suppose \(E|\log |\eta_0^*|| - \log \sigma| - E|\log |\eta_0^*|| = 0,\) that is, in view of (46), \(E\{(\log \sigma - \log |\eta_0^*|)\mathbf{1}_{0 < \log |\eta_0^*| < \log \sigma}\} = 0.\)

Then, because the variable under the expectation is nonnegative, \(\log \sigma = \log |\eta_0^*|\) or \(\mathbf{1}_{0 < \log |\eta_0^*| < \log \sigma} = 0,\text{ a.s.}\) We are led to a contradiction, because \(\log |\eta_0^*|\) has a positive density on some interval \((0, \epsilon)\) with \(\epsilon > 0.\) The case \(\sigma < 1\) can be handled similarly. Result ii) straightforwardly follows and the proof of iii) being standard, it is omitted.

Now we turn to the asymptotic normality. Following the lines of proof of Davis, Knight and Liu (Lemma 2.2 and Remark 1, 1992), it can be shown that
\[
\sqrt{n}\left(\hat{\theta}_n^* - \theta_0^*\right) = -\xi_r \sqrt{n} \sum_{t=1}^{n} \left(\mathbf{1}_{\eta_t^* > M} - \mathbf{1}_{\eta_t^* < M}\right) \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2(\theta_0^*)}{\partial \theta} + o_P(1)
\]
\[
\xi_r \sim N(0, \xi_r^2 J^{-1}_r). \quad (47)
\]
This asymptotic distribution was obtained by Peng and Yao (2003) under similar assumptions, in particular C0. Similar to (26) we have
\[
\sqrt{n}(\hat{\mu}_n^* - \mu_0^*) = \frac{1}{\sqrt{n}} \sum_{t=1}^{n} |\eta_t^*|^r - \mu_0^* - \frac{r}{2} E|\eta_t^*|^r \Omega^* \sqrt{n}(\hat{\theta}_n^* - \theta_0^*) + o_P(1)
\]
\[
= M^{-r/2} \left( \frac{1}{\sqrt{n}} \sum_{t=1}^{n} |\eta_t^*|^r - \frac{r}{2} \Omega^* \sqrt{n}(\hat{\theta}_n^* - \theta_0^*) + o_P(1) \right).
\]
We have
\[
\text{Cov}\left(\sqrt{n}\left(\hat{\theta}_n^* - \theta_0^*\right), \frac{1}{\sqrt{n}} \sum_{t=1}^{n} |\eta_t^*|^r - 1\right) = -\delta_r \xi_r^2 J^{-1}_r \Omega^* + o(1).
\]
It follows that
\[ \text{Cov}\left( \sqrt{n}\left( \hat{\theta}_n^* - \theta_0^* \right), \sqrt{n}\left( \hat{\mu}_r^* - \mu_r^* \right) \right) = -a_r J_*^{-1} \Omega_* + o(1). \]

We also have
\[ \text{Var}\left( \sqrt{n}\left( \hat{\mu}_r^* - \mu_r^* \right) \right) = \frac{1}{M^r} \left\{ E|\eta_t|^2r - 1 + r \xi_0^2 \left( \frac{r \xi_0^2}{4} + \delta_r \right) \right\} + o(1). \]

using (8), which obviously holds with \( \theta_0^* \) replaced by \( \theta_0^{**} \).

The case \( r = 0 \) is handled similarly, using the expansion
\[ \sqrt{n}(\hat{\mu}_0^* - \mu_0^*) = \frac{1}{\sqrt{n}} \sum_{t=1}^n (\log |\eta_t| - E \log |\eta_t|) - \frac{1}{2} \Omega_*^r \sqrt{n}(\hat{\theta}_n^* - \theta_0^{**}) + o_P(1). \]

\[ \frac{\partial G_r(\theta_0^*, \mu_0^*)}{\partial (\theta', \mu)} = \left[ \begin{matrix} \frac{2}{r} \xi_0^2 r^2 & 2 \xi_0^2 \Omega_r^* \end{matrix} \right], \quad A^* = \left( \begin{array}{cc} I_{q+1} & 0 \\ 0 & M I_p \end{array} \right). \]

Using (38), the asymptotic variance
\[ \text{Var}_a\left\{ \sqrt{n}\left( \hat{\theta}_{n,h} - \theta_0 \right) \right\} - \text{Var}_a\left\{ \sqrt{n}\left( \tilde{\theta}_n - \theta_0 \right) \right\} = \left[ \begin{matrix} 2 \xi_0^2 \left( \frac{r \xi_0^2}{4} - 1 \right) - \xi_0^2 \left( J^{-1} - \bar{\sigma}_0^2 \right) \end{matrix} \right]. \]

and the equivalence between (16) and (17) is deduced from (44).

Remark 9 follows from Theorem B.2 and
\[ \left( \frac{\partial G_0(\theta_0^*, \mu_0^*)}{\partial (\theta', \mu)} \right) = \left[ \begin{array}{cc} 1 & 2 \xi_0^2 \end{array} \right]. \]

The ARE of the one-step QMLE relative to the two-step LADE only depends on the innovations distribution and is illustrated in Figure 3.
Predictions of powers of ARCH

ν = 10
ν = 12
ν = 14

Fig. 3. Same as Figure 1 for the two-step LAD estimator.

B.6. Procedure in the case \( r = 0 \)

When \( r = 0 \), that is for the prediction of \( \log |\epsilon_{n+1}| \), the procedure can be modified as follows, starting from Step 2, in view of Remarks 7 and 9.

Step 2. Compute the rescaled residuals \( \hat{\eta}_t^* = \frac{\hat{\epsilon}_t}{\hat{\sigma}_t^*} \). Compute the empirical moment \( \hat{\mu}_4^* \) of these residuals, and the empirical mean and variance of the log-absolute residuals, \( \hat{E}(\log |\eta|) \) and \( \hat{\text{Var}}(\log |\eta|) \) respectively. Compute the empirical median \( \hat{M}^* \), and estimate the density \( \hat{f}_{\eta^2} \) of the \( \hat{\eta}_t^* \).

Step 3. Compute the quantities

\[
c_0 = \frac{\hat{\mu}_4^*}{\hat{\mu}_2^*} - 1, \quad c_1 = 4\hat{\text{Var}}(\log |\eta|), \quad c_2 = \frac{1}{\{2\hat{M}^*\hat{f}_{\eta^2}(\hat{M}^*)\}^2}.
\]

(i) If \( c_0 = \min_{i=0,1,2} c_i \), then the Gaussian QMLE can be preferred for the prediction of \( \log |\epsilon_{n+1}| \). The prediction is computed as \( \log \hat{\sigma}_n + \hat{E}(\log |\eta|) \).

(ii) If \( c_2 = \min_{i=0,1,2} c_i \), then the LADE can be preferred. Reestimate the model by LAD, and compute the \( \hat{\eta}_t^{**} = \frac{\hat{\epsilon}_t}{\hat{\sigma}_t^{**}} \). Compute the empirical mean \( \hat{E}(\log |\eta^{**}|) \) of the log-absolute residuals. The prediction of \( |\epsilon_{n+1}| \) is \( \log \hat{\sigma}_{n}^{**} + \hat{E}(\log |\eta^{**}|) \).

(iii) If \( c_1 = \min_{i=0,1,2} c_i \), then the one-step estimator can be preferred. Reestimate the model by non-gaussian QML, by minimizing

\[
\sum_{t=1}^{n} \left\{ \log \left( \frac{|\epsilon_t|}{\hat{\sigma}_t(\theta)} \right) \right\}^2.
\]

The prediction of \( |\epsilon_{n+1}| \) is \( \log \hat{\sigma}_n \).

B.7. Comparison of the two-step QMLE and LADE

We have seen that the asymptotic relative efficiency of the two-step QML with respect to the two-step LAD method for predicting \( |\epsilon_{n+1}| \) does not depend on \( r \). To see how it depends
on the distribution of $\eta_t$, we show the ARE for GED and Student distributions in Figure 4. As expected, the right graph shows that the LADE is preferable for fat tailed distributions. The left graph shows that for distributions close to the Gaussian or the Laplace, the QML is asymptotically better; when $\nu$ increases, the tails increase for the GED and the LADE tends to be the best.

B.8. Simulation experiments

The first set of simulation experiments aims to compare the effective relative efficiencies of the 1-step method based on the generalized QMLE, the 2-step method based on the QMLE and the 2-step method based on the LADE. We simulated $N = 500$ independent trajectories of size $n = 10200$ of GARCH(1,1) models $\epsilon_t = \sigma_t \eta_t$, in which $\eta_t$ follows the generalized error distribution with $\nu$ degrees of freedom, GED($\nu$). The GARCH parameters have been chosen in such a way to obtain, for all values of $r$ and $\nu$, the usual parameterization

$$\begin{cases} 
    \epsilon_t = \sigma_t^* \eta_t^*, & E\eta_t^{2*} = 1 \\
    \sigma_t^{*2} = 1 + 0.05\sigma_{t-1}^* + 0.7\sigma_{t-1}^{*2}.
\end{cases}$$

For each of the $N$ simulations, the first $n_1 = 200$ values were used to estimate the GARCH parameters and the moments required by the last two methods. The last $n_2 = 10000$ values were used to compute the mean square prediction errors (MSPE) given, in the case $r \neq 0$, by

$$\frac{1}{n_2} \sum_{t=n_1}^{n_2-1} (|\epsilon_{t+1}| - P_{t,h})^2, \quad \frac{1}{n_2} \sum_{t=n_1}^{n_2-1} (|\epsilon_{t+1}| - P_t^*)^2, \quad \frac{1}{n_2} \sum_{t=n_1}^{n_2-1} (|\epsilon_{t+1}| - P_t^{**})^2$$

where $P_{t,h} = \tilde{\sigma}^r(\epsilon_n, \ldots, \epsilon_1; \hat{\theta}_{n_1,h})$ are the one-step predictions and $P_t^* = \tilde{\sigma}^r(\epsilon_1, \ldots, \epsilon_1; \hat{\theta}_{n_1}^*)\hat{\mu}_r^*$ and $P_t^{**} = \tilde{\sigma}^r(\epsilon_1, \ldots, \epsilon_1; \hat{\theta}_{n_1}^{**})\hat{\mu}_r^{**}$ are the two-step predictions based respectively on the
Table 4. Percentages of MSPE losses with respect to the unfeasible optimal predictor, for predicting the power $r$ of a GARCH(1,1) model with $\eta_t \sim GED(\nu)$.

Gaussian QMLE and the LADE. These MSPE have been compared to those obtained with the naive predictor $\hat{\sigma}'(\epsilon_1, \ldots, \epsilon_1; \hat{\theta}_0^n)$ and with the (approximated$^9$) optimal predictor $\hat{\sigma}'(\epsilon_n, \ldots, \epsilon_1; \theta_0)$. As expected, the minimal MSPE were always obtained with the optimal predictor. Table 4 gives the percentages of relative MSPE losses with respect to the optimal predictor over the $N$ replications. As expected, the naive predictor entails important efficiency losses, except in the case $r = 2$ where this method coincides with the 1-step GQMLE and with the 2-step QMLE. Obviously, Table 4 confirms that the naive method must be avoided. In accordance with the asymptotic theory (see Remark 8), the ranking of the 2-step QML and 2-step LAD methods does not depend on $r$, the LADE is preferred when $\nu$ is large (i.e. $\nu = 3$) and the QML is slightly better when $\nu = 0.1$ or $\nu = 0.5$, whereas the two methods are almost equivalent when $\nu = 2$. As expected from Figures 1-3, the 1 step method is the best for all the values of $\nu$ and $r$ considered in Table 4, except for $r = 2$ and $\nu = 3$ where the method based on the LAD is much more efficient.

In a second set of simulation experiments, we assess the effective performance of the adaptive method. We simulated $N = 500$ independent trajectories of size $n = 10500$ of a GARCH(1,1) model, with 3 different designs for the parameter $(\omega_0, \alpha_0, \beta_0)$ and for the distribution of the noise $\eta_t$. For each trajectory, the first 500 observations are used to estimate the GARCH models and the relevant moments of the noise, whereas the last 10000 values are used to compute the percentages of MSPE for predicting a given power $r$ by the different methods. In Design A, $\eta_t$ follows a multimodal distribution, a mixture of 3 normal distributions of the form

$$\eta_t \sim \pi \phi(x) + \frac{1 - \pi}{2} \phi(x + m) + \frac{1 - \pi}{2} \phi(x - m),$$

where $\phi(\cdot)$ denotes the standard gaussian density. We took $\pi = 1/2$ and $m = 10$, so that the distribution of $\eta_t$ is such that $c_2$ is much greater than $c_0$ and $c_1$. Table 5 displays the percentages of MSPE losses with respect to the best prediction method among the four methods employed, that is, the naive, 1-step, 2-step and adaptive procedures. For Design A, we chose $\alpha_0 = 0.10$ and $\beta_0 = 0.8$ (the results are not sensitive to the value of $\omega_0$), and we took $r = 1.5$. Of course, similar results are obtained for other choices of the parameters.

$^9$This estimator is said to be an "approximation" of the optimal predictor because it is based on a finite number of past values. It is introduced as a benchmark but it can not be used in practice because $\theta_0$ is unknown.
Table 5. Percentages of MSPE losses with respect to the asymptotically optimal prediction method.

</tr>
</tbody>
</table>

Table 5 confirms that, as expected the LADE is much less efficient than the other methods for that design. In Design B, the distribution of \( \eta_t \) is chosen to be the Cauchy distribution. We also chose \( r = 0.45 \), so that the moment of order \( 2r \) exist, as required with the 1-step method. Since the dispersion of the noise is high, the GARCH parameter should be chosen smaller than in Design A to obtain a strict stationary solution. We thus took \( \alpha_0 = 0.005 \) and \( \beta_0 = 0.8 \). This design should penalize the 2-step QML method because the required moments do not exist. Indeed, Table 5 shows that the 2-step QML method induces an important efficiency loss. In Design C keeps the parameters of Design B, except that \( \eta_t \) follows a mixture distribution of the form (48), where \( \phi(\cdot) \) is replaced by the Cauchy density. As expected, the best method is the 1-step method in that case. Interestingly, the adaptive method is always close to the optimal method in terms of MSPE. Table 6 gives the number of times that each method is selected by the adaptive method. In the framework of Design A, the adaptive method always makes the right choice. In Designs B and C, the adaptive method often makes suboptimal choices, but the MSPE is however close to the optimal.

B.9. Complementary empirical results

In this section we come back to the prediction problem of the daily returns of the 10 world stock market indices of Section 5. We study the sensitivity of the results to i) a change of model, and to ii) a change of period for the data sets. Because stationarity is crucial for our results, we start by considering this issue.

B.9.1. Stationarity of returns

Figure 5 displays the sample paths of the CAC, DAX, FTSE, Nikkei, SMI and SP500 prices and returns. Similar graphs were obtained for the 4 other indices. While the non stationarity of prices is clear from these drawings, the sample paths of returns are compatible with stationarity. This is confirmed by Figure 6 showing the empirical autocorrelations of such returns. The significance bands computed for a GARCH(1,1)10 show that these autocorrelations are compatible with a GARCH(1,1) model for the returns. In the GARCH(1,1) framework, a formal test of strict stationarity can be done. Applying the test developed by

\[ \text{See Francq and Zakoian (2009). The R-code can be downloaded at http://www.runmycode.org/CompanionSite/site.do?siteid=23.} \]
Franq and Zakoian (2012), we conclude that the stationarity cannot be rejected, at any reasonable significance levels, for the returns.

B.9.2. Complement to Table 3
For \( n_1 = n_2 = n_3 = 300 \), Table 7 displays the percentages of prediction losses with respect to the best method, for \( r = -0.5 \), \( r = 0 \), \( r = 0.5 \), \( r = 1 \), \( r = 1.5 \) and \( r = 2 \).

B.9.3. Using a standard GARCH instead of a TARCH
We first re-estimate the ARE of the methods assuming a standard GARCH(1,1) model

\[
\epsilon_t = \sigma_t \eta_t, \quad \sigma_t^2 = \omega_0 + \alpha_0 \epsilon_{t-1}^2 + \beta_0 \sigma_{t-1}^2,
\]

instead of the TGARCH(1,1) model (49). Figure 7 is very similar to Figure 2, which leads again to the conclusion that the one-step method is often the most efficient when \( r \in (0.5, 2) \), but is always dominated when \( r > 2 \) or \( r \) is small.

Note that Figures 2 and 7 do not directly compare the ARE of the 2-step LAD with respect to the 2-step Gaussian GMLE. These ARE do not depend on \( r \), but just on the distribution of the iid noise. Table 8 indicates that the ranking of the 2 method may depend on the volatility model, but for the 5 European indices the LADÉ is often expected to be more efficient than the QMLE, whereas this is the opposite for the 5 other indices.
Fig. 6. Empirical autocorrelation functions of the CAC, DAX, FTSE, Nikkei, SMI and SP500 returns. Standard significance bands (at the level 95%) of a strong white noise are displayed in dotted lines, significance bands for a GARCH(1,1) process are displayed in solid lines.

Fig. 7. Estimated ARE’s of the one-step QMLE relative to the two-step QMLE (left panel) and LAD estimator (right panel) for stock index returns. As Figure 2, but the volatility model is the GARCH(1,1) model (49) instead of the TGARCH(1,1) model (49).
Table 7. Percentages of MSPE losses with respect to the best method, for prediction of $|\epsilon_{n+1}|^r$.

Table 9 and Table 7 are very similar, except that the relative MSPE losses of the Naive and Historic methods are globally more important for the TGARCH than for the standard GARCH. The Historic method being model-free, larger losses with respect to the adaptive method based on the TGARCH than with the one based on the standard GARCH is an indicator that the TGARCH model does a slightly better job for the predictions. For the two models, the adaptive method is clearly the most efficient.

B.9.4. Using a subperiod of the data set

Figure 8 and Tables 10 are respectively similar to Figure 7 and Table 9, except that the data cover the period from January 2, 1990, to January 22, 2009. The results are not much affected by the fact that the period does not include anymore the recent sovereign-debt crises in Europe and US.

Table 11 presents results similar to those of Table 10 but for empirical means based on 30 returns (instead of 250) in the historical method. For $r = -0.5$ the results worsen. For positive values of $r$ the results are generally better with 30 observations, but the adaptive method remains superior (the percentages being always equal or very close to zero).

B.9.5. Duration models

The dynamics of duration between stock price changes has attracted much attention in the econometrics literature. Engle and Russell (1998) proposed the Autoregressive Conditional Duration (ACD) model, which assumes that the duration between price changes has the dynamics of the square of a GARCH:

\[
\begin{align*}
&x_t = \psi_1 \eta_t, \quad (\eta_t) \sim \text{iid} \\
&\psi_t = \omega_0 + \sum_{k=1}^q \alpha_{0k} x_{t-k} + \sum_{j=1}^p \beta_{0j} \psi_{t-j}
\end{align*}
\]

(50)

with \( \omega_0 > 0, \alpha_{0k} \geq 0, \beta_{0j} \geq 0 \). An alternative specification that does not constrain the sign of the coefficients is the logarithmic ACD proposed by Bauwens and Giot (2000), which can be written as follows:

\[
\begin{align*}
&x_t = e^{\phi_1 \eta_t}, \quad (\eta_t) \sim \text{iid} \\
&\phi_t = \omega_0 + \sum_{k=1}^q \alpha_{0k} \log x_{t-k} + \sum_{j=1}^p \beta_{0j} \phi_{t-j}
\end{align*}
\]

(51)

It is clear that both ACD models are of the form (1). Figure 9 displays the empirical autocorrelation functions for the absolute returns of the SP500, the inverse absolute returns of the SP500, IBM durations data, and the inverse IBM durations. For the stock index the absolute returns appear strongly autocorrelated, showing that a GARCH-type model is compatible with the autocorrelations.

B.10. The Asymmetric Power GARCH\((p, q)\) case

Pan, Wang and Tong (2008) established that the strict stationarity condition writes \( \gamma(B_0) < 0 \), where \( \gamma(B_0) \) is the top-Lyapunov exponent associated to Model (14). This condition entails the invertibility of the polynomial \( B_0(z) \) and allows to write the model under the form (1). It also ensures the existence of \( E|\epsilon_t|^s \) for some \( s > 0 \).

With obvious notation, Assumption B1 holds with

\[
F(\theta, K) = (K^d \omega, K^d \alpha_1, K^d \alpha_1, \ldots, K^d \alpha_q, \beta_1, \ldots, \beta_p)'.
\]

Hamadeh and Zakoïan (2011) showed that the following assumption entails AN of the Gaussian QMLE of \( \theta_0 = (\omega_0, \alpha_{01}, \ldots, \alpha_{0q}, \beta_{01}, \ldots, \beta_{0p})' \).

**D:** \( \gamma(B_0) < 0; \forall \theta \in \Theta, \quad \sum_{j=1}^d \beta_j < 1 \) and \( \omega > \omega \) for some \( \omega > 0 \); if \( P(\eta_t \in \Gamma) = 1 \) for a set \( \Gamma \), then \( \Gamma \) has a cardinal \( |\Gamma| > 2 \); \( P(\eta_t > 0) \in (0, 1) \); if \( p > 0 \), \( B_0(z) \) has no common root with \( A_{\theta_0+}(z) \) and \( A_{\theta_0-}(z) \). Moreover \( A_{\theta_0+}(1) + A_{\theta_0-}(1) \neq 0 \) and \( \alpha_{0q,+} + \alpha_{0q,-} + \beta_{0p} \neq 0 \).

**Theorem B.3 (Asymmetric Power GARCH\((p, q)\)).** Let \( r \neq 0 \). For \( h \in C(r) \), 

\[ E|\eta_0|^r = 1, E|\eta_0|^{2r} < \infty \] and under **D**, the one-step estimator of \( \theta_0 \in \Theta \) satisfies (11). Under the same assumptions and \( En_0^r < \infty \), the two-step estimator is given by \( \hat{\theta}_n = (\hat{\mu}_0^*, \hat{\mu}_1^*, \ldots, \hat{\mu}_q^*, \ldots, \hat{\sigma}_1^*, \ldots, \hat{\sigma}_p^*) \) and satisfies

\[
\sqrt{n} (\hat{\theta}_n - \theta_0) \xrightarrow{d} N \left( 0, (\kappa_4 - 1)J^{-1} + \left( \frac{\delta}{2} \right)^2 \left( \frac{2r}{\kappa_4^*} \right)^2 \left( \frac{\kappa_4^r}{\kappa_4^*} - 1 \right) \right) \frac{\theta_0^*}{\theta_0^0}
\]
Fig. 9. Empirical autocorrelation functions for: i) absolute returns of the SP500 (top left), ii) inverse absolute returns of the SP500 (top right). iii) IBM durations (bottom left), i) inverse IBM durations (bottom right)
where \( \tilde{\theta}_0 = \left( \theta_0^{[1:2q+1]} \right) \), \( \theta_0^{[1:2q+1]} = (\omega_0, \alpha_{01}, \ldots, \alpha_{0q-1})' \).

Moreover, the conclusion of Corollary 2 holds true for Model (14): the estimator \( \tilde{\theta}_n \) is asymptotically more efficient than \( \hat{\theta}_{n,h} \) iff (13) holds.

**Proof.** To prove the AN, we have already seen in the proof of Theorem 3.2 that Assumptions A4 and A7 are satisfied with \( \delta = r \). Assumptions A5 and A8 are satisfied by the same arguments as in Theorem 3.2 and using Pan, Wang and Tong (2008), and Hamadeh and Zakoïan (2011). The latter paper also established the second part of A2 and A9. The AN follows from Theorem 2.1.

Because \( G_r(\theta_0', \mu_0') = (\omega_0, \alpha_{01} + \alpha_{01}, \ldots, \alpha_{0q-1}, \beta_0 + \beta_0, \ldots, \beta_{p_0})' \) we have

\[
\begin{bmatrix}
\frac{\partial G_r(\theta_0', \mu_0')}{\partial \theta'} \\
\frac{\partial G_r(\theta_0', \mu_0')}{\partial \mu}
\end{bmatrix} = \begin{bmatrix}
\mu_{2} \Delta \delta \\
\delta / \mu_{2} \Delta \end{bmatrix}, \quad \Delta = \begin{pmatrix}
I_{2q+1} & 0 \\
0 & \mu_{2} I_p
\end{pmatrix}.
\]

Similarly to (33), the derivatives of \( \sigma_t^2(\theta) \) verify

\[
\begin{align*}
B_\theta(L) \frac{\partial \sigma_t^2}{\partial \omega}(\theta) & = 1, \\
B_\theta(L) \frac{\partial \sigma_t^2}{\partial \alpha_{i+}}(\theta) & = (\epsilon_{t-i})^2, \\
B_\theta(L) \frac{\partial \sigma_t^2}{\partial \alpha_{i-}}(\theta) & = (-\epsilon_{t-i})^2, \quad i = 1, \ldots, q, \\
B_\theta(L) \frac{\partial \sigma_t^2}{\partial \beta_j}(\theta) & = \sigma_t^2, \quad j = 1, \ldots, p.
\end{align*}
\]

It follows that, similarly to (38)

\[
J_\delta^{-1} \Omega_\delta = \overline{\theta}_0, \quad \Omega_\delta' J_\delta^{-1} \Omega_\delta = 1
\]

where

\[
J_\delta = E \left( \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2}{\partial \theta} \frac{\partial \sigma_t^2}{\partial \theta'}(\theta_0) \right) = \left( \frac{\delta}{2} \right)^2 J, \quad \Omega_\delta = E \left( \frac{1}{\sigma_t^2} \frac{\partial \sigma_t^2}{\partial \theta'}(\theta_0) \right) = \frac{\delta}{2} \Omega.
\]

Thus

\[
J_\delta^{-1} \Omega = \frac{\delta}{2} \overline{\theta}_0, \quad \Omega_\delta' J_\delta^{-1} \Omega = 1
\]

Moreover, similarly to (34), we have

\[
\frac{\partial \sigma_t^2(\theta_0)}{\partial \theta} = \mu_2^{-1/2} A_3 \frac{\partial \sigma_t^2(\theta_0)}{\partial \theta}.
\]

It follows that, similar to (35),

\[
J_* = \mu_2^{-3/2} A_3 J_\delta, \quad \Omega_* = \mu_2^{-3/2} A_3 \Omega.
\]

Hence, the asymptotic variance of Theorem 3.1 is given by

\[
\begin{pmatrix}
J_* & \Omega_* \\
\Omega_*' & J_*
\end{pmatrix} = \begin{pmatrix}
(\kappa_4 - 1) \mu_2^{-1/2} A_3 J_*^{-1} A_3^{-1} & -\lambda_4 \mu_2^{-1/2} A_3^{-1} J_*^{-1} \Omega' \\
-\lambda_4 \mu_2^{-1/2} \Omega_*' J_*^{-1} A_3^{-1} & \sigma_\mu^2
\end{pmatrix}
\]
Therefore, the asymptotic variance of the reparameterized QMLE of the two-step approach

\[
\Gamma_r = \begin{bmatrix}
\mu_2^{-\frac{\delta}{r}} A_\delta & \delta \frac{\mu_2^{-\frac{\delta}{r}}}{\mu_2 A_\delta} \\
\frac{\mu_2^{-\frac{\delta}{r}} A_\delta'}{\mu_2 A_\delta} & \frac{\mu_2^{-\frac{\delta}{r}} A_\delta' A_\delta}{\mu_2 A_\delta}
\end{bmatrix} \Sigma_r \begin{bmatrix}
\mu_2^{-\frac{\delta}{r}} A_\delta & \delta \frac{\mu_2^{-\frac{\delta}{r}}}{\mu_2 A_\delta} \\
\frac{\mu_2^{-\frac{\delta}{r}} A_\delta'}{\mu_2 A_\delta} & \frac{\mu_2^{-\frac{\delta}{r}} A_\delta' A_\delta}{\mu_2 A_\delta}
\end{bmatrix}
\]

\[
= (\kappa_4 - 1) J^{-1} - \lambda_r \delta \frac{\mu_2^{-\frac{\delta}{r}}}{\mu_2} \left( \Omega J^{-1} + J^{-1} \Omega \right) + \sigma_{\mu^2}^2 \left( \delta \frac{\mu_2^{-\frac{\delta}{r}}}{\mu_2} \right)^2 \theta_0 \theta_0'.
\]

In view of (53), the asymptotic variance follows.

Finally, the conclusion of Corollary 2 holds true for Model (14), since

\[
\text{Var}_{\text{as}} \left\{ \sqrt{n} \left( \hat{\theta}_{n,h} - \theta_0 \right) \right\} - \text{Var}_{\text{as}} \left\{ \sqrt{n} \left( \tilde{\theta}_n - \theta_0 \right) \right\}
= \left[ \left( \frac{2}{r} \right)^2 \left( \frac{\kappa_2 r}{\kappa_4 r^2} - 1 \right) - (\kappa_4 - 1) \right] \left( J^{-1} - \left( \frac{\delta}{2} \right)^2 \theta_0 \theta_0' \right)
\]

and

\[
J^{-1} \geq \left( \frac{\delta}{2} \right)^2 \theta_0 \theta_0'.
\]
